1 Java SE 9 Introduction

2 Classes

The class is the logical construct upon which the Java language is built because it defines the shape and nature of an object, and therefore forms the basis for object-oriented programming in Java.

2.1 Class Fundamentals

A class defines a new data type. Once defined, this new type can be used to create objects of that type. A class is therefore a *template* for an object, and an *object* is an *instance* of a class. *Object* and *instance* are often used interchangeably.

2.1.1 General Form of a Class

When you define a class, you declare its exact form and nature. You do this by specifying the data that it contains and the code that operates on that data. A class is declared by use of the class keyword.

```
class classname {
  type instance-variable1;
  type instance-variable2;
  ...
  type instance-variableN;

  type method-name1 (parameter-list {
    body of method
  }

  type method-name2 (parameter-list {
    body of method
  }
  ...
  type method-nameN (parameter-list {
    body of method
  }
}
```

GeneralForm 2.1: Class Declaration — General Form

The data, or variables, defined within a class are called *instance variables*. The code is contained within *methods*. Collectively, the methods and variables defined within a class are called *members* of the class. In most cases, the instance variables are acted upon and accessed by the methods defined for that class. As a general rule, it is the methods that determine how a class' data can be used.

Each instance of the class (that is, each object of the class) contains its own copy of the instance variables. The data for one object is separate and unique from the data for another. Changes to the instance variables of one object have no effect on the instance variables of another.

Java classes do not need to have a 'main()' method; you only need to specify one if that class is the starting point for the program.

In general, you use the *dot operator* to access both the instance variables and the methods within an object. Although commonly referred to as the dot *operator*, the formal specification for Java categorizes the . as a *separator*.

2.2 Declaring Objects

Because a class creates a new data type, you can use this type to declare objects of that type. Obtaining objects of a class is a two-step process.

- 1. Declare a variable of the class type; this variable does not define an object. Instead, it is simply a variable that can *refer* to an object.
- 2. Acquire an actual, physical copy of the object and assign it to the variable; you can do this using the new operator. The new operator dynamically allocates (at run time) memory for an object, and returns a reference to to. This reference is (essentially) the address in memory of the object allocated by new. This reference is then stored in the variable. In Java, all class objects must be dynamically allocated.

Example Declaration, Allocation, and Assignment

```
Box mybox; // 1. declare a variable
mybox = new Box(); // 2. allocate a Box object
```

These two declarations can be combined into a single declaration, and usually are:

```
Box mybox = new Box();
```

The mybox variable simply holds the memory address of the actual Box object. The class name followed by parenthese specifies the *constructor* for the class.

2.3 Methods

General Form of a Method Declaration

```
type name (parameter-list) {
  body of method
}
```

GeneralForm 2.2: Method Declaration — General Form

type specifies the type of data returned by the method. This can be any valid type, including class types that you create. If the method does not return a value, its return type must be void.

name is the name of the method. This can be any legal identifier.

parameter-list is a sequence of type and identifier pairs separated by commas. Parameters are essentially variables that receive the value of the arguments passed to the method when it is called. If the method has no parameters, then the parameter list will be empty.

Methods that have a return type other than **void** return a value to the calling routine using a return statement:

```
return value
```

where *value* is the value returned.

2.4 Constructors

Java allows objects to initialize themselves when they are created. This automatic initialization is performed through the use of a constructor.

A constructor initializes an object immediately upon creation. It has the same name as the class in which it resides and is syntactically similar to a method. Once defined, the constructor is automatically called when the object is created, before the new operator completes. Constructors have no return type. It is the constructor's job to initialize the internal state of an object so that the code creating an instance will have fully initialized, usable object immediately.

2.5 The this Keyword

Sometimes a method will need to refer to the object that invoked it. To allow this, Java defines the this keyword. this can be used inside any method to refer to the *current* object. That is, this is always a reference to the object on which the method was invoked. You can use this anywhere a reference to an object of the current class' type is permitted.

2.5.1 Instance Variable Hiding

It is illegal to declare two local variables with the same name inside the same or enclosing scope. However, you can have local variables, including formal parameters to methods, which overlap with the names of the class' instance variables. For these cases, the local variables *hide* the instance variables of the same name.

Because this lets you refer directly to the object, you can use it to resolve any namespace collisions that might occur between instance variables and local variables. So, this.width = width is an example of a local variable (width) hiding an instance variable (also width), with this allowing an assignment between them.

2.6 A Stack Class

To see a practical application of object-oriented programming, here is one of the archetypal examples of encapsulation: the stack. A stack stores data using first-in, last-out ordering. That is, a stack is like a stack of plates on a table — the first plate put down on the table is the last plate to be used. Stacks are controlled through two operations traditionally called push and pop. To put an item on top of the stack, you will use push. To take an item off the stack, you will use pop. It is easy to encapsulate the entire stack mechanism.

Here is a class called Stack that implements a stack for up to ten integers, plus test class called TestStack:

3 Methods and Classes

This chapter examines several topics relating to methods and classes, including

- overloading
- parameter passing
- recursion
- access control
- keywords static and final
- String class
- Arrays
- nested and inner classes
- command-line arguments and varargs

3.1 Overloading Methods

It is possible to define two or more methods within the same class that share the same name as long as their parameter declarations are different. When this is the case, the methods are said to be *overloaded*, and the process is referred to as *method overloading*. Method overloading is one of the ways that Java supports polymorphism.

When an overloaded method is invoked, Java uses the type and number of arguments as its guid to determine which version of the overloaded method to actually call. Thus, overloaded methods must differ in the type or number of their parameters. While overloaded methods may have different return types, their eturn type alone is inusfficient to distinguish two versions of a method. When Java encounters a call to an overloaded method, it simply executes the version of the method whose parameters match the arguments used in the call.

The match between arguments and parameters need not always be exact. In some cases, Java's automatic type conversions can play a role in overload resolution. For example, if there is a method with one double parameter, and that method is invoked with a single int argument, then, when no exact match is found, Java will automatically convert the integer into a double, and this conversion will be used to resolve the call. Java will employ automatic type conversion only if no exact match is found.

Method overloading supports polymorphism because it is one way that Java implements the one interface, multiple methods paradigm. That is, Java does not need to rename each similar method just because it has a slightly different parameter requirements. The value of overloading is that it allows related methods to be accessed by use of a common name, representing the general action that is being performed, and leaves to the compiler the choice of the right specific version for a particular circumstance. The programmer need only remember the general operation being performed. Through the application of polymorphism, several names have been reduced to one. Overloading can help manage greater complexity.

3.1.1 Overloading Constructors

You can also overload constructor methods.

3.2 Objects as Parameters

It is both correct and common to pass objects to methods as well as primitive types. One of the most common uses of object parameters involves constructors. Frequently you will want to construct a new object so that it is initially the same as some existing object. To do this, you must define a constructor that takes an object of its class as a parameter. Providing many forms of constructors is usually required to allow objects to be constructed in a convenient and efficient manner.

3.3 Argument Passing

In general, there are two ways that a computer language can pass an argument to a sub-routine:

- 1. call-by-value
- 2. call-by-reference

Java uses call-by-value to pass all arguments, although the precise effect differs between whether a primitive type or a reference type is passed.

When you pass a primitive type to a method, it is passed by value. Thus, a copy of the argument is made, and what occurs to the parameter that receives the argument has no effect outside the method.

When you pass an object to a method, the situation changes; objects are passed by what is effectively call-by-reference. When you pass a variable of a class type, you pass a reference to the method and the parameter receiving it will refer to the same object. This effectively means that objects act as if they are passed to methods by use of call-by-reference. Changes to the object inside the method do affect the object used as an argument. However, when an object reference is passed to a method, the reference itself is passed by use of call-by-value; therefore, that reference will continue to refer to the object, even though the object itself may be modified.

3.4 Returning Objects

A method can return any type of data, including class types that you create.

Since all objects are dynamically allocated using new, you don't need to worry about an object going out-of-scope because the method in which it was created terminates. The object will continue to exist as long as there is a reference to it somewhere in your program. When there are no references to it, the object will be reclaimed the next time garbage collection takes place.

3.5 Recursion

Recursion is the process of defining something in terms of itself. In programming, it is also what allows a method to call itself. A method that calls itself is said to be recursive.

When a method calls itself, new local variables and parameters are allocated storage on the stack, and the method code is executed with these new variables from the start. As each recursive call returns, the old local variables and parameters are removed from the stack, and execution resumes at the point of the call inside the method. Recursive versions of many routines may execute a bit slower than the iterative equivalent because of the added overhead of the additional method calls. A large number of recursive calls to a method could cause a stack overrun. Because storage for parameters and local varibles is on the stack and each new call creates a new copy of these variables, it is possible that the stack could be exhausted. If this occurs, the Java run-time system will cause an exception.

The main advantage to recursive methods is that they can be used to create clearer and simpler versions of several algorithms than can their iterative relatives. For example, the QuickSort sorting algorithm is quite difficult to implement in an iterative way. Also, some types of AI-related algorithms are most easily implemented using recursive solutions.

3.6 Access Control

Encapsulation provides another important attribute besides linking data with code: access control. Through encapsulation, you can control what parts of a program can access the members of a class. By controlling access, you can prevent misuse. Thus, when correctly implemented, a class creates a black box which may be used, but the inner workings of which are not open to tampering. The classes introduced earlier do not completely meet this goal. For example, the Stack class provides the methods push() and pop() as a controlled interface to the stack, this interface is not enforced — it is possible for another part of the program to bypass these methods and access the stack directly. This could lead to trouble.

How a member can be accessed is determined by the access modifier attached to its declaration. Java supplies a rich set of access modifiers. Some aspects of access control are related mostly to inheritance or packages (and now modules). Those ideas will be discussed later. Here, let's examine access control as it relates to a single class.

Access Modifiers

Java's access modifiers are:

- public
- private
- protected (applies only to inheritance)
- default access level

public vs private Access

When a member of a class is modified by public, then that member can be accessed by any other code. When a member of a class is specified as private, then that member can only be accessed by other members of its class. Thus, the method main() is always preceded by the public modifier. It must be called by code that is outside the program — the Java run-time system.

Default Access — No Access Modifier

When no access modifier is used, then by default the member of a class is public within its own package, but cannot be accessed outside of its package. In the classes developed so far, all members of a class have used the default access mode. However, this is typically

not what you will want to be the case. Usually, you will want to restrict access to the data members of a class — allowing access only through methods. There will also be times when you will want to define methods that are private to a class.

Access Modifier Syntax

An access modifier precedes the rest of a member's type specification. That is, it must begin a member's declaration statement. As an example:

```
public int i;
private double j;

private int myMethod(int a, char b) {
    ...
}
```

Access Control and Inheritance

Consult the chapter on Chapter 4 "Inheritance", page 18, for more on the topic of access control in relation to inheritance.

3.6.1 An Improved Stack Class

StackImproved.java

The following table lists called chunk definition points.

```
Chunk name

<Stack Constructor>

<Stack Instance Methods>

<Stack Private Instance Variables>

First definition point

See "Stack Constructor Subsection", page 7.

See "Stack Instance Methods Subsection", page 7.

See "An Improved Stack Class", page 13.
```

Stack Private Instance Variables

```
<Stack Private Instance Variables> =
  /* Now, both stck and tos are private. This means
        that they cannot be accidentally or maliciously
        altered in a way that would be harmful to the stack.
        */
        private int[] stck = new int[10];
```

 $^{^{1}\,}$ Notice how all of the prior code except what is changed can easily be reused using TexiWebJr's modular system.

```
private int tos;
```

This chunk is called by {StackImproved.java}; see its first definition at "An Improved Stack Class", page 13.

Now both stck, which holds the stack, and tos, which is the index of the top of the stack, are specified as private. This means that they cannot be accessed or altered except through push() and pop(). Making tos private, for example, prevents other parts of your program from inadvertently setting it to a value that is beyond the end of the stck array. In other words, the following code, added to the end of the TestStack.java program (see "Stack TestStack Subsection", page 8), would be illegal and the program would not compile:

```
mystack1.tos = -2;
mystack2.stck[3] = 100;
```

3.7 static Keyword

There will be times when you want to define a class member that will be used independently of any object of that class. Normally, a class member must be accessed in conjunction with an object of its class. However, it is possible to create a member that can be used by itself without reference to a specific instance. To create such a member, precede its declaration with the keyword static. When a member is declared static, it can be accessed before any objects of its class are created, and without reference to any object.

You can declare both methods and variables to be static. Instance variables declared as static are essentially global variables. When objects of its class are declared, no copy of a static variable is made. Instead, all instances of the class share the same static variable.

Restrictions on static Methods

Methods declared as static have several restrictions:

- they can only directly call other static methods of their class;
- they can only directly access static variables of their class;
- they cannot refer to this or super in any way;

static Block

If you need to do computation in order to initialize your static variables, you can declare a static block that gets executed exactly once, when the class is first loaded (static initialization block).

```
class UseStatic {
  static int a = 3;
  static int b;

static {
   b = a * 4;
  }
}
```

As soon as the UseStatic class is loaded, all of the static statements are run. First, a is set to '3', then the static block executes and initializes b to 'a * 4' or '12'. Then main() is called (not shown).

Use of static Members Outside Their Class

Outside of the class in which they are defined, static methods and variables can be used independently of any object. To do so, you need only specify the name of their class followed by the dot operator: classname.method(). classname is the name of the class in which the static method is declared. A static variable can be accessed in the same way. This is how Java implements a controlled version of global methods and global variables.

3.8 final Keyword

A field can be declared as final. Doing so prevents its contents from being modified, making it, esentially, a constant. This means that you must initialize a final field when it is declared. You can do this in one of two ways: when it is declared, or within a constructor.

In addition to fields, both method parameters and local variables can be declared as final. Declaring a parameter as final prevents it from being changed within the method. Declaring a local variable final prevents it from being assigned a value more than once.

The keyword final can also be applied to methods, but its meaning is different than when applied to variables. This usage of final is described in the next chapter (see Chapter 4 "Inheritance", page 18).

3.9 Arrays Revisited

Arrays are implemented as objects. Because of this, there is a special array attribute that you will want to take advantage of. Specifically, the size of an array—that is, the number of elements that an array can hold—is found in its length instance variable. All arrays have this variable, and it will always hold the size of the array. Keep in mind that the value of length has nothing to do with the number of elements that are actually in use. It only reflects the number of elements taht the array is designed to hold.

3.10 Nested and Inner Classes

It is possible to define a class within another class; such classes are known as nested classes. The scope of a nested class is bounded by the scope of its enclosing class. A nested class does not exist independently of its enclosing class. A nested class has access to the members, including private members, of the enclosing class. However, the enclosing class does not have access to the members of the nested class. A nested class that is declared directly within its enclosing class scope is a member of its enclosing class. It is also possible to declare a nested class that is local to a block.

Static Nested Class

There are two types of nested class: *static* and *inner*. A static nested class is one that has the **static** modifer applied. Because it is static, it must access the non-static members of its enclosing class through an object. That is, it cannot refer to non-static members of its enclosing class directly. Static nested classes are seldom used.

Inner Class

The most important type of nested class is the *inner* class. An inner class is a non-static nested class. It has access to all of the variables and methods of its outer class and may refer to them directly in the same way that other non-static members of the outer class do.

An instance of an inner class can be created only in the context of its enclosing class. The Java compiler will report an error otherwise. In general, an inner class instance is often created by code within its enclosing scope.

It is possible to define inner classes within any block scope, including within the block defined by a method or even within the body of a for loop.

Handling Events

While nested classes are not applicable to all situations, they are particularly helpful when handling events. See Chapter 18 "Event Handling", page 117. There are also anonymous inner classes, inner classes that don't have a name.

3.11 The String Class

Every string you create is an object of type String. Even string constants are String objects. For example, in the statement System.out.println("This is a String, too");, the quote is a String object.

Objects of type String are immutable; once a String object is created, its contents cannot be altered. Java defines peer classes of String, called StringBuffer and StringBuilder, which allow strings to be altered, so all of the normal string manipulations are still available.

Constructing String Objects and Concatenating Strings

Strings can be constructed in a variable of ways. The easiest is to use a statement:

```
String myString = "this is a test";

Java defines one operator for String objects: +. It is used to concatenate two strings.

String myString = "I" + " like " + "Java.";
```

String Methods

The String class contains several methods that you can use.

- boolean equals(secondStr)
- int length()
- char charAt(index)

3.12 Using Command-Line Arguments

Sometimes you will want to pass information into a program when you run it. This is accomplished by passing *command-line arguments* to main(). A command-line argument is the information that directly follows the program's name on the command line when it is executed. To access the command-line arguments inside a Java program, access the String

arguments passed to the args parameter of main(). The first command-line argument is stored at args[0], the second at args[1], and so on. All command-line arguments are passed as strings. You must convert numeric values to their internal forms manually. See Chapter 12 "java.lang", page 84.

3.13 Varargs: Variable-Length Arguments

Beginning with JDK 5, Java has included a feature that simplifies the creation of methods that need to take a variable number of arguments. This feature is called *varargs* and it is short for *variable-length arguments*. A method that takes a variable number of arguments is called a *variable-arity method*, or simply *varargs method*.

A variable-length argument is specified by three period (...). For example: static void vaTest (int ... v) {. This syntax tells the compiler that vaTest() can be called with zero or more arguments. As a result, v is implicitly declared as an array of type int[]. Thus, inside vaTest(), v is accessed using the normal array syntax.

A method can have *normal* parameters along with a variable-length parameter, but the variable-length parameter must be the final parameter declared by the method. Further, there can be only one varargs parameter.

```
int doIt(int a, int b, double c, int ... vals) {
```

After the first three arguments, any remaining arguments are passed to vals.

Overloading Vararg Methods

You can overload a method that takes a variable-length argument (i.e., it can be given a different type, or additional parameters can be included, or a non varargs parameter).

Note that unexpected errors can result when overloading a method that takes a variable-length argument. These errors involve ambiguity because it is possible to create an ambiguous call to an overloaded varargs method. In such a case, the program will not compile. While each individual method declaration might be valid, the call might yet be ambiguous.

4 Inheritance

Inheritance is a cornerstone of object-oriented programming because it allows the creation of hierarchical classifications. Using inheritance, you can create a general class that defines traits common to a set of related items. This class can then be inherited by other, more specific classes, each adding those things that are unique to them.

A class that is inherited is called a *superclass*. The class that does the inheriting is called a *subclass*. A subclass is a specialized version of a subclass. It inherits all of the members defined by the superclass and adds its own, unique elements.

4.1 Inheritance Basics

To *inherit* a class, incorporate the definition of one class into another by using the extends keyword.

```
class A {...}
class B extends A {...}
```

A subclass will include all of the members of its superclass. The subclass can directly reference all of the members of the superclass as well. Subclasses can be superclasses of other subclasses.

General Form of a Subclass Inheriting a Superclass

```
class subclass-name extends superclass-name { body\ of\ class }
```

GeneralForm 4.1: Subclass General Form

A subclass can have only one superclass. Java does not support the inheritance of multiple superclasses into a single subclass.

4.1.1 Member Access and Inheritance

Although a subclass includes all of the members of its superclass, it cannot access those members of the superclass that have been declared as private. A class member that has been declared as private will remain private to its class. It is not accessible by any code outside its class, including subclasses.

A major advantage of inheritance is that once you have created a superclass that defines the attributes commoin to a set of objects, it can be used to create any number of more specific subclasses. Each subclass can precisely tailor its own classification.

4.1.2 A Superclass Variable Can Reference a Subclass Object

A reference variable of a superclass can be assigned a reference to any subclass derived from that superclass.

It is important to understand that it is the type of the reference variable — not the type of the object that it refers to — that determines what members can be accessed. That is, when a reference to a subclass object is assigned to a superclass reference variable, you will have access only to those parts of the object defined by the superclass. The superclass has no knowledge of what a subclass adds to it.

4.2 Using super

Whenever a subclass needs to refer to its immediate superclass, it can do so by use of the keyword super. super has two general forms. The first calls the superclass' constructor. The second is used to access a member of the superclass that has been hidden by a member of a subclass.

4.2.1 Using super to Call Superclass Constructors

A subclass can call a constructor defined by its superclass by use of the following form of super:

```
super(arg-list);
```

GeneralForm 4.2: super Calling a Constructor

arg-list specifies any arguments needed by the constructor in the superclass. super() must always be the first statement executed inside a subclass' constructor. super() can be called using any form defined by the superclass.

4.2.2 super Referencing Superclass

The second form of super acts somewhat like this, except that it always refers to the superclass of the subclass in which it is used.

```
super.member
```

GeneralForm 4.3: super Referencing its Superclass

member can be either a method or an instance variable. This form of **super** is most applicable to situations in which member names of a subclass hide members by the same name in the superclass.

```
i = super.i;
```

super allows access to the i defined in the superclass. super can also be used to call methods that are hidden by a subclass.

4.3 Creating a Multilevel Hierarchy

You can build hierarchies that contain as many layers of inheritance as you like. It is acceptable to use a subclass as a superclass of antoher. Each subclass inherits all of the traits found in all of its superclasses.

super always refers to the constructor in the closest superclass.

While an entire class hierarchy can be created in a single file, the individual classes (superclasses and subclasses) can be placed into their own files and compiled separately. Using separate files is the norm, not the exception, in creating class hierarchies.

4.4 When Constructors are Executed

In a class hierarchy, constructors complete their execution in order of derivation, from superclass to subclass.

4.5 Method Overriding

In a class hierarchy, when a method in a subclass has the same name and type signature as a method in its superclass, then the method in the subclass is said to *override* the method in the superclass. When an overriden method is called from within its subclass, it will always refer to the version of that method defined by the subclass. The version of the method defined by the superclass will be hidden.

If you wish to access the superclass version of an overridden method, you can so by using super.

Method overriding occurs *only* when the names and the type signatures of the two methods are identical. If they are not, then the two methods are simply overloaded (no name hiding takes place).

4.6 Dynamic Method Dispatch

Method overriding forms the basis for one of Java's most powerful concepts: dynamic method dispatch. This is a meachanism by which a call to an overrident method is resolved at run time, rather than compile time. This is important because this is how Java implements run-time polymorphism.

A superclass reference variable can refer to a subclass object. Java uses this fact to resolve calls to overriden methods at run time. When an overriden method is called through a superclass reference, Java determines which version of that method to execute based upon the type of the object being referred to at the time the call occurs. Thus, this determination is made at run time. When different types of objects are referred to, different versions of an overridden method will be called. In other words, it is the type of the object being referred to (not the type of the reference variable) that determines which version of an overridden method will be executed. Therefore, if a superclass contains a method that is overridden by a subclass, then when different types of objects are referred to through a superclass reference variable, different versions of the method are executed.

4.6.1 Why Overridden Methods?

Overridden methods allow Java to support run-time polymorphism. Polymorphism is essential to object-oriented programming for one reason: it allows a general class to specify methods that will be common to all of its derivatives, while allowing subclasses to define the specific implementation of some or all of those methods. Overridden methods are another way that Java implements the "one interface, multiple methods" aspect of polymorphism.

Successfully applying polymorphism is understanding that the superclasses and subclasses form a hierarchy which moves from lesser to greater specialization. Used correctly, the superclass provides all elements that a subclass can use directly. It also defines those methods that the derived class must implement on its own. This allows the subclass the flexibility to define its own methods, yet still enforces a consistent interface. Thus, by combining inheritance with overridden methods, a superclass can define the general form of the methods that will be used by all of its subclasses.

Dynamic, run-time polymorphism is one of the most powerful mechanisms that objectoriented design brings to bear on code reuse and robustness. The ability of existing code libraries to call methods on instances of new classes without recompiling while maintaining a clean abstract interface is a profoundly powerful tool.

4.6.2 Applying

Let's look at a practical example that uses method overriding. The following program creates a superclass called Figure that stores the dimensions of a two-dimensional object. It also defines a method called area() that computes the area of an object. The program derives two subclasses from Figure. The first is Rectangle and the second is Triangle. Each of these subclasses overrides area() so that it returns the area of a rectangle and a triangle respectively.

```
 \{ \texttt{FindAreas.java} \} \equiv \\ < \textit{FindAreas SuperClass Figure} > \\ < \textit{FindAreas SubClass Rectangle} > \\ < \textit{FindAreas SubClass Triangle} > \\ < \textit{FindAreas Main Class} > \\
```

The following table lists called chunk definition points.

Output

The output from the program should be:

```
Inside Area for Rectangle.
Area is 45
Inside Area for Triangle.
Area is 40
Area for Figure is undefined.
Area is 0
```

Through the dual mechanisms of inheritance and run-time polymorphism, it is possible to define one consistent interface that is used by several different, yet related, types of objects. In this case, if an object is derived from Figure, then its area can be obtained by calling area(). The interface to this operation is the same no matter what type is being used.

4.6.2.1 FindAreas Superclass Figure Section

```
<FindAreas SuperClass Figure > ≡
    class Figure {
        <Figure Instance Variable Declarations >
        <Figure Constructor >

4.7 Using Abstract Classes

There are situations in which you will want to define a superclass that declares the structure of a given abstraction without providing a complete implementation of every method. That is, sometimes you will wnat to create a superclass that only defines a generalized form that will be shared by all of its subclasses, leaving it to each subclass to fill in the details. Such a class determines the nature of the methods that the subclasses must implement. One way this situation can occur is when a superclass is unable to create a meaningful implementation for a method. This is the case with Figure in the preceding example. The definition of area() is simply a placeholder. It will not compute and display the area of any type of object.

It is not uncommon for a method to have no meaningful definition in the context of its superclass. Java's solution to this problem is the abstract method.

You can require that certain methods be overridden by subclasses by specifying the abstract type modifier. These methods are sometimes referred to as *subclasser responsibility* because they have no implementation specified in the superclass. Thus, a subclass must override them — it cannot simply use the version defined in the superclass.

To declare an abstract method, use the general form:

abstract type name (parameter-list);

GeneralForm 4.4: Abstract Method Declaration—General Form

No method body is present.

Any class that contains one or more abstract methods must also be declared abstract. To declare a class abstract, simply use the abstract keyword in front of the class keyword at the beginning of the class declaration. There can be no objects of an abstract class. That is, an abstract class cannot be directly instantiated with the new operator. You cannot declare abstract constructors or abstract static methods. Any subclass of an abstract class must either implement all of the abstract methods in the superclass, or be declared abstract itself. Abstract classes can include fully implemented methods.

Abstract Classes Can Be Reference Variables

Although abstract classes cannot be used to instantiate objects, they can be used to create object references, because Java's approach to run-time polymorphism is implemented through the use of superclass references. Thus, it must be possible to create a reference to an asbtract class so that it can be used to point to a subclass object.

4.7.1 Improved Figure Class

Using the abstract class, you can improve the Figure class. Since there is no meaningful concept of area for an undefined two-dimensional figure, the following version of the program declares area() as abstract inside Figure. This means that all classes derived from Figure must override area().

```
 \{ \texttt{AbstractAreas.java} \} \equiv \\ < AbstractAreas \ Abstract \ Class \ Figure > \\ < FindAreas \ SubClass \ Rectangle > \\ < FindAreas \ SubClass \ Triangle > \\ < AbstractAreas \ Main \ Class > \\ \end{aligned}
```

The following table lists called chunk definition points.

4.7.1.1 AbstractAreas Abstract Class Figure Section

Notice that much of this class stays the same as the original Figure code, but includes two abstract declarations, one for the class, and one for the area() method declaration.

```

      <Figure Instance Variable Declarations >

Create Basic Figure Objects Except Figure

The only difference here is that because the superclass Figure is now abstract, it cannot be instantiated using new. It can, however, be used as a reference variable, and so the declaration Figure figref; is still valid and does not change from the prior implementation. This is the essence of run-time polymorphism and dynamic method dispatch.

```
<Create Basic Figure Objects Except Figure > =
   // abstract class Figure cannot be instantiated
   // Figure f = new Figure (10, 10);
   Rectangle r = new Rectangle (9, 5);
   Triangle t = new Triangle (10, 8);
```

Call Overridden Methods One By One Except Figure

The only difference here is that, because there is no Figure object, it cannot be referenced. <*Call Overridden Methods One By One Except Figure* > ≡

```
figref = r;
System.out.println("Area is " + figref.area());
```

```
figref = t;
System.out.println("Area is " + figref.aread());

// there is no Figure object, so this will not work.
// figref = f;
```

4.8 Using final with Inheritance

The keyword final has three uses.

- 1. create the equivalent of a name constant.
- 2. prevent overriding
- 3. prevent inheritance

4.8.1 Using final to Prevent Overriding

There will be times when you want to prevent overriding from occurring. To disallow a method from being overridden, specify final as a modifier at the start of its declaration. Methods declared as final cannot be overridden.

Methods declared as final can sometimes provide a performance enhancement. The compiler is free to *inline* calls to them because it knows they will not be overridden by a subclass. Inlining is an option only with final methods. Normally, Java resolves calls to methods dynamically, at run time. This is called *late binding*. However, since final methods cannot be overridden, a call to one can be resolved at compile time. This is called *early binding*.

4.8.2 Using final to Prevent Inheritance

Sometimes you will want to prevent a class from being inherited. To do this, precede the class declaration with final. Declaring a class as final implicitly declares all of its methods as final also.

4.9 The Object Class

There is one special class, Object, defined by Java. All other classes are subclasses of Object. That is, Object is a superclass of all other classes. This means that a reference variable of type Object can refer to an object of any other class. Also, since arrays are implemented as classes, a variable of type Object can also refer to any array.

Object Methods

Object defines the following methods; this means they are available in every object.

Object clone()

Creates a new object that is the same as the object being cloned.

boolean equals(Object object)

Determines whether one object is equal to another.

void finalize()

Called before an unused object is recycled. (Deprecated by JDK 9).

Class<?> getClass()

Obtains the class of an object at run time.

int hashCode()

Returns the hash code associated with the invoking object.

void notify()

Resumes execution of a thread waiting on the invoking object.

void notifyAll()

Resumes execution of all threads waiting on the invoking object.

String toString()

Returns a string that describes the object.

void wait()

void wait(long milliseconds)

void wait(long millisconds, int nanoseconds)

Waits on another thread of execution

The methods

- getClass()
- notify()
- notifyAll()
- wait()

are declared as final. You may override the others.

However, notice two methods now:

equals() compares two objects; returns true if the objects are equal, and false if not; the precise definition of equality can vary, depending on the type of objects being compared.

toString()

returns a string that contains a description of the object on which it is called; this method is automatically called when an object is output using println(); many classes override this method; doing so allows them to tailor a description specifically for the types of objects that they create.

5 Packages

Packages are containers for classes. They are used to keep the class namespace compartmentalized, i.e., to prevent collisions between file names. Packages are stored in a hierarchical manner and are explicitly imported into new class definitions.

5.1 Introduction to Packages

Java provides a mechanism for partitioning the class namespace into manageble chunks: the *PACKAGE*. The package is both a naming and a visibility control mechanism. In other words, you can use the package mechanism to define classes inside a package that are not accessible by code outside the package; and you can define class members that are exposed only to other members of the same package.

5.2 Defining Packages

To create a package ("define" a package), include the package command as the first statement in a Java source file. Thereafter, any classes declared within that file will belong to the specified package. The package statement defines a namespace in which classes are stored. Without the package statement, classes are put into the default package (which has no name).

General Form of package statement

```
package pkg

GeneralForm 5.1: Package Statement — General Form pkg is the name of the package. For example:

package mypackage;
```

File System Directories

Java uses the file system directories to store packages. Therefore, the .class files for any classes you declare to be part of mypackage must be stored in a directory called mypackage. The directory name must match the package name exactly.

More than one file can include the same package statement. The package statement simply specifies to which package the classes defined in a file belong. It does not exclude other classes in other files from being part of that same package. Most real-world packages are spread across many files.

Hierarchy of Packages

You can create a hierarch of packages. To do so, separate each package name form the one above it by use of a period. The general form of a multileveled package statement is:

```
package pkg1[.pkg2[.pkg3]]
GeneralForm 5.2: Package Statement — Multilevel Form
```

A package hierarchy must be reflected in the file system of your Java development system. For example a package declared as:

```
package a.b.c;
```

needs to be stored in directory a/b/c.

Be sure to choose package names carefully; you cannot rename a package without renaming the directory in which the classes are stored.

5.3 Finding Packages and CLASSPATH

Packages are mirrored by directories. How does the Java run-time system know where to look for packages?

'cwd'

By default, the Java run-time system uses the currect working directory as its starting point. Thus, if your package is in a subdirectory of the current directory, it will be found.

CI.ASSPATH

You can specify a directory path or paths by setting the CLASSPATH environment variable.

-classpath

You can use the -classpath option with java and javac to specify the path to your classes.

module path

Beginning with JDK 9, a package can be part of a module, and thus found on the module path.

Example Finding a Package

Consider the following package specification:

```
package mypack;
```

In order for programs to find mypack, the program can be executed from a directory immediadely above mypack, or the CLASSPATH must be set to include the path to mypack or the -classpath option must specify the path to mypack when the program is run via java.

When the second or third of the above options is used, the class path must not include mypack itself. It must simply specify the path to just above mypack. For example, if the path to mypack is

```
/MyPrograms/Java/mypack
then the class path to mypack is
/MyPrograms/Java
```

5.4 Packages and Member Access

Packages add another dimension to access control. Classes and packages are both means of encapsulating and containing the name space and scope of variables and methods. *Packages* act as containiners for classes and other subordinate packages. *Classes* act as containers for data and code. The class is Java's smallest unit of abstraction. As it relates to the interplay between classes and packages, Java addresses four categories of visibility for class members:

- Subclasses in the same package
- Non-subclasses in the same package

- Subclasses in different packages
- Classes that are neither in the same package nor subclasses

The three access modifiers

- private
- public
- protected

provide a variaty of ways to produce many levels of access required by these categories.

Category	Private	None	Protected	public
Same Class	Yes	Yes	Yes	Yes
Same package subclass	No	Yes	Yes	Yes
Same package non-subclass	No	Yes	Yes	Yes
Different package subclass	No	No	Yes	Yes
Different package noni-subclass	No	No	No	Yes

Table 5.1: Package Access Table — Shows all combinations of the access control modifiers

5.5 Importing Packages

Java includes the import statement to bring certain classes, or entire packages, into visibility. Once imported, a class can be referred to directly, using only its name. The import statement is a convenience to the programmer and is not technically needed to write a complete Java program.

In a Java source file, import statements occur immediately following the package statement (if one exists) and before any class definitions. This is the general form of the import statement:

```
import pkg1[.pkg2].(classname \mid *);
GeneralForm 5.3: Import Statement — General Form
```

Here, pkg1 is the name of a top-level package, and pkg2 is the name of a subordinate package inside the outerpackage separated by a dot (.). There is no limit on the depth of a package hierarchy. Finally, you can specify either an explicit classname or a star (*), which indicates that the Java compiler should import the entire package.

```
import java.util.Date;
imort java.io.*;
```

All of the standard Java SE classes included with Java begin with the name java. The basic language functions are stored in a package called java.lang. Normally, you have to import every package or class that you want to use, but since Java is useless without much of the functionality in java.lang, it is implicitly imported by the compiler for all programs. This is equivalent to the following line being at the top of all your programs:

```
import java.lang.*;
```

The import statement is *optional*. Any place you use a class name, you can use its *fully qualified name*, which includes its full package hierarchy.

When a package is imported, only those items within the package declared as public will be available to non-subclasses in the importing code.

6 Interfaces

Using the keyword interface, you can fully abstract a class' interface from its implementation. That is, using interface, you can specify what a class must do, but not how to do it. Interfaces are syntactically similar to classes, but they lack instance variables, and, as a general rule, their methods are declared without any body. Once it is defined, any number of classes can implement an interface. Also, one class can implement any number of interfaces. To implement an interfece, a class must provide the complete set of methods required by the interface. Each class is free to determine the details of its own implementation. By providing the interface keyword, Java allws you to fully utilize the "one interface, multiple methods" aspect of polymorphism.

Version 0.2.7

Interfaces are designed to support dynamic method resolution at run time. Normally, in order for a method to be called from one class to another, both classes need to be present at compile time so the Java compiler can check to ensure that the method signatures are compatible. This requirement by itself makes for a static and nonextensible classing environment. Inevitably in a system like this, functionality gets pushed up higher and higher in the class hierarchy so that the mechanisms will be available to more and more subclasses. Interfaces are designed to avoid this problem. They disconnect the definition of a method or set of methods from the inheritance hierarchy. Since interfaces are in a different hierarchy from classes, it is possible for classes that are unrelated in terms of class hierarchy to implement the same interface. This is where the real power of interfaces is realized.

6.1 Defining Interfaces

An interface is defined much like a class. Here is a simplified general form of an interface definition:

```
access interface name {
  return-type method-name1(parameter-list);
  return-type method-name2(parameter-list);

  type final-varname1 = value
    type final-varname2 = value
    ...
  return-type method-nameN(parameter-list);
  type final-varnameN = value
}
```

GeneralForm 6.1: Interface Definition — Simplified General Form

When no access modifier is included, then default access results, and the interface is only available to other members of the package in which it is declared. When it is declared as public, the interface can be used by code outside its package. In this case, the interface must be the only public interface declared in the file, and the file must have the same name as the interface. The methods that are declared have no bodies. They end with a semicolon after the parameter list. They are, essentially, abstract methods. Each class that includes such an interface must implement all of the methods.

Variable Declarations inside Interfaces

As the general form shows, variables can be declared inside interface declarations. They are implicitly final and static, meaning they cannot be changed by the implementing class. They must also be initialized. All methods and variables are implicitly public.

6.2 Implementing Interfaces

Once an interface has been defined, one or more classes can implement that interface. To implement an interface, include the implements clause in a class definition, and then create the methods required by the interface. The general form of a class that includes the implements clause looks like this:

```
class clasname [extends superclass] [implements interface [, interface. . . ] { class-body }
```

GeneralForm 6.2: Class Implementing Interface — General Form

The methods that implement an interface must be declared public. The type signature of the implementing method must match exactly the type signature specified in the interface definition.

It is both permissible and common for classes that implement interfaces to define additional members of their own.

6.3 Accessing Implementations Through Interface References

You can declare variables as object references that use an interface rather than a class type. Any instance of any class that implements the declared interface can be referred to by such a variable. When you call a method through one of these references, the correct version will be called based on the actual instance of the interface being referred to. This is one of the key features of interfaces. The method to be executed is looked up dynamically at run-time, allowing classes to be created later than the code which calls methods on them. The calling code can dispatch through an interface without having to know anything about the "callee." This process is similar to using a superclass reference to access a subclass object.

6.4 Partial Implementations

If a class includes an interface but does not implement the methds required by that interface, then that class must be declared as abstract. Any class that inherits the abstract class must implement the interface or be declared abstract itself.

6.5 Nested Interfaces

An interface can be declared a member of a class or another interface. Such an interface is called a *member interface* or a *nested interface*. A nested interface can be declared as public, private, or protected. This differs from a top-level interface, which must either be declared as public or use the default access level. When a nexted interface is used

outside of its enclosing scope, it must be qualified by the name of the class or interface of which it is a member. Thus, outside of the class or interface in which a nested interface is declared, its name must be fully qualified.

6.6 Applying Interfaces

See detailed example . . .

6.7 Variables in Interfaces

You can use interfaces to import shared constants into multiple classes by simply declaring an interface that contains variables that are initialized to the desired values. When you include that interface in a class (when you "implement" the interface), all of those variable names will be in scope as constants. If an interface contains no methods, then any class that includes such an interface doesn't actually implement anything. It is as if that class were importing this constant fields into the class name space as final variables.

6.8 Interfaces Can Be Extended

One interface can inherit another by use of the keyword extends. The syntax is the same as for inheriting classes. When a class implements an interface that inherits another interface, it must provide implementations for all methods required by the interface inheritance chain.

6.9 Default Interface Methods

Prior to JDK 8, an interface could not define any implementation whatsoever. This meant that for all previous versions of Java, the methods specified by an interface were abstract, constaining no body. This is the traditional form of an interface. The release of JDK 8 changed this by adding a new capability to interface called the *default method*. A default method lets you define a default implementation for an interface method. It is possible for an interface method to provide a body, rather than being abstract.

A primary motivation for the default method was to provide a means by which interfaces could be expanded without breaking existing code. There must be implementations for all methods defined by an interface. If a new method were added to a popular, widely used interface, then the addition of that method would break existing code because no implementation would be found for that new method. The default method solves this problem by supplying an implementation that willbe used if no other implementation is explicitly provided. Thus, the addition of a default method will not cause preexisting code to break.

Another motivation for the default method was the desire to specify methods in an interface that are, essentially, optional, depending on how the interface is used.

Interfaces Do No Maintain State and Cannot Be Created

It is important to point out that the addition of default methods does not change a key aspect of interface: its inability to maintain state information. An interface still cannot have instance variables, for example. Thus, the defining difference between an interface and a class is that a class can maintain state information, but an interface cannot. Furthermore,

it is still not possible to create an instance of an interface by itself. It must be implemented by a class.

6.10 Use Static Methods in an Interface

Another capability added to interface by JDK 8 is the ability to define one or more static methods. Like static methods in a class, a static method defined by an interface can be called independently of any object. Thus, no implementation of the interface is necessary, and no instance of the interface is required, in order to call a static method. Instead, a static method is called by specifying the interface name, followed by a period, followed by the method name. Here is the general form:

Interface Name.static Method Name

GeneralForm 6.3: Interface Static Method, Calling

Notice that this is similar to the way that a static method in a class is called. However, static interface methods are not inherited by either an implementing class or a subinterface.

6.11 Private Interface Methods

Beginning with JDK 9, an interface can include a private method. A private interface method can be called only by a default method or another private method defined by the same interface. Because a private interface method is specified **private**, it cannot be used by code outside the interface in which it is defined. This restriction includes subinterfaces because a private inteface method is not inherited by a subinterface.

The key benefit of a private interface method is that it lets two or more default methods use a common piece of code, thus avoiding code duplication.

7 I/O

This chapter introduces <code>java.io</code>, which supports Java's basic input/output system, including file I/O. Support for I/O comes from Java's core API libraries, not from language keywords. In this chapter the foundation of this subsystem is introduced so that you can see how it fits into the larger context of the Java programming and execution environment. This chapter also looks at the <code>try-with-resources</code> statement.

7.1 I/O Basics

Most real applications of Java are not text-based, console programs. Rather, they are either graphically oriented programs that rely on one of Java's graphical user interface (GUI) frameworks, such as Swing, the AWT, or JavaFX, for user interaction, or they are Web applications. Text-based console programs do not constitute an important use for Java in the real world. Java's support for console I/O is limited and somewhat awkword to use. Text-based console I/O is just not that useful in real-world Java programming.

Java does, however, provide strong, flexible support for I/O as it relates to files and networks. Java's I/O system is cohesive and consistent. A general overview of I/O is presented here. A detailed description is found in chapters describing the Java Library: See Chapter 15 "Input/Output — java.io", page 89, and See Chapter 16 "NIO", page 115.

7.1.1 Streams

Java programs perform I/O through streams. A stream is an abstraction that either produces or consumes information. A stream is linked to a physical device by the Java I/O system. All streams behave in the same manner, even if the actual physical device to which they are linked differ. Thus, the same I/O classes and methods can be applied to different types of devices. This means that an input stream can abstract many different kinds of input; from a disk file, a keyboard, or a network socket. Likewise, an output stream may refer to the console, a disk file, or a network connection. Java implements streams within class hierarchies defined in the java.io package.

7.1.2 Byte Streams and Character Streams

Java defines two types of streams:

- byte streams
- character streams

Byte streams provide a convenient means for handling input and output of bytes. Byte streams are used when reading or writing binary data. Character streams provide a convenient means for handling input and output of characters. They use Unicode and therefore can be internationalized. In some cases, character streams are more efficient than byte streams.

The original version of Java (Java 1.0) did not include character streams and thus all I/O was byte-oriented. Character streams were added by Java 1.1 and certain byte-oriented classes and methods were deprecated.

At the lowest level, all I/O is still byte-oriented. The character-based streams simply provide a convenient and efficient means for handling characters.

7.1.2.1 The Byte Stream Class

Byte streams are defined by using two class hierarchies. At the top are two abstract classes:

- InputStream
- OutputStream

Each of these abstract classes has several concrete subclasses that handle the differences among various devices, such as disk files, network connections, and memory buffers. The byte stream classes in java.io are shown in Table 7.1.

To use the stream classes, you must import java.io.

BufferedInputStream

 ${\tt BufferedOutputStream}$

Buffered input and output streams

ByteArrayInputStream

ByteArrayOutputStream

Input and Output streams that read from and write to a byte array

DataInputStream

DataOutputStream

Input and Output streams that contain methods for reading and writing the Java standard data types

FileInputStream

FileOutputStream

Input and Output streams that read from and write to a file

FilterInputStream

FilterOutputStream

Implements InputStream and OutputStream

InputStream

OutputStream

Abstract classes that describe stream input and output

ObjectInputStream

ObjectOutputStream

Input and Output streams for objects

PipedInputStream

PipedOutputStream

Input and Output pipe

PrintStream

Output stream that contains print() and println()

PushbackInputStream

Input stream that allows bytes to be returned to the input stream

SequenceInputStream

Input stream that is a combination of two or more input streams that will be read sequentially, one after the other

Table 7.1: The Byte Stream Classes in java.io

The abstract classes InputStream and OutputStream define several key methods that the other stream classes implement. Two of the most important are:

- read()
- write()

which respectively read and write bytes of data. Each has a form that is abstract and must be overridden by derived stream classes.

7.1.2.2 The Character Stream Class

Character streams are defined by using two class hierarchies. At the top are two abstract classes:

- Reader
- Writer.

These abstract classes handle Unicode character streams. Java has several concrete subclasses of these. The character stream classes in java.io are shown in Table 7.2.

BufferedReader

BufferedWriter

Buffered input and output character streams

CharArrayReader

CharArrayWriter

Input and Output streams that read and write to and from a character array

FileReader

FileWriter

Input and Output streams that read from and write to a file

FilterReader

FilterWriter

Filtered read and writer

InputStreamReader

OutputStreamWriter

Input and Output streams that translate bytes to characters

LineNumberReader

Input stream that counts lines

PipedReader

PipedWriter

Input and Output pipes

PrintWriter

Output stream that contains print() and println()

PushbackReader

Input stream that allows characters to be return to the input stream

Reader

Writer Abstract clases the describe character stream input and output

StringReader

StringWriter

Input and output streams that read from and write to a string

Table 7.2: The Character Stream I/O Classes in java.io

The abstract classes Reader and Writer define several key methods that the other stream classes implement. Two of the most important methods are:

- read()
- write()

which read and write characters of data, respectively. Each has a form that is abstract and must be overridden by derived stream classes.

7.1.2.3 The Predefined Streams

The java.lang package defines a class called System, which encapsulates several aspects of the run-time environment. System contains three predefined stream variables:

- 1. in (standard input), an object of type InputStream
- 2. out (standard output), an object of type PrintStream
- 3. err (standard error), an object of type PrintStream

These fields are declared as public, static, and final within System. This means that they can be used by any other part of your program and without reference to a specific System object. While these are all byte streams, they can be wrapped within character-based streams, if desired.

7.2 Reading Console Input

For commercial applications, the preferred method of reading console input is to use a character-oriented stream. This makes your program easier to internationalize and maintain.

System.in Wrapped in BufferedReader

Console input is accomplished by reading from System.in To obtain a character-based stream that is attached to the console, wrap System.in in a BufferedReader object. BufferedReader supports a buffered input stream. A commonly-used constructor is:

BufferedReader(Reader inputReader)

Here, *inputReader* is the stream that is linked to the instance of BufferedReader that is being created. Reader is the abstract class. One of its concrete subclasses is InputStreamReader, which converts bytes to characters. To obtain a InputStreamReader object that is linked to System.in, use the following constructor:

InputStreamReader(InputStream inputStream)

Because System.in refers to an object of type InputStream, it can be used for *inputStream*. Putting it all together, the following line of code creates a BufferedReader that is connected to the keyboard:

```
BufferedReader br = new BufferedReader(
  new InputStreamReader(System.in));
```

After this statement executes, **br** is a character-based stream that is linked to the console through System.in.

7.2.1 Reading Characters

To read a character from a BufferedReader, use read(). The version of read() that we will be using is

int read() throws IOException

Each time that read() is called, it reads a character from the input stream and returns it as an integer value.¹ It returns -1 when an attempt is made to read at the end of the stream. It can throw an IOException.

Program Demonstrating Reading Characters from Console

The following program demonstrates read() by reading characters from the console until the user types a "q". Any I/O exceptions that might be generated are simply thrown out of main(). In more sophisticated applications, you can handle the exceptions explicitly.

```
\{ BRRead.java \} \equiv \\ < Import java.io > \\ class BRRead \{ \\ public static void main(String[] args[]) throws IOException \{ \\ < BRRead BufferedReader Constructor > \\ < BRRead Enter Characters > \\ \} \\ \}

```
<BRRead Enter Characters> =
    char c;
    do {
        c = (char) br.read();
        System.out.println(c);
    } while (c != 'q');
```

This chunk is called by {BRRead.java}; see its first definition at "Reading Characters", page 44.

7.2.2 Reading Strings

To read a string frmo the keyboard, use the version of readLine() that is a member of the BufferedReader class. Its general form is:

String readLine() throws IOException

It returns a String object.

Program Demonstrating Reading a String from Console

The following program demonstrates BufferedReader and the readLine() method; the program reas and displays lines of text until the word "stop" is entered.

```
 \{ BRReadLines.java \} \equiv \\ < Import \ java.io > \\ \\ class \ BRReadLines \ \{ \\ public \ static \ void \ main(String[] \ args) \ throws \ IOException \ \{ \\ < BRReadLines \ BufferedReader \ Constructor > \\ < BRReadLines \ Enter \ Lines > \\ \} \\ \}
```

<BRReadLines BufferedReader Constructor> =
   // create a BufferedReader using System.in
BufferedReader br = new BufferedReader(
   new InputStreamReader(System.in))
```

7.2.2.2 BRReadLines Enter Lines

```
<BRReadLines Enter Lines> \(\)
String str;

System.out.println("Enter lines of text.");
System.out.println("Enter 'stop' to quit.");

do {
    str = br.readLine();
    System.out.println(str);
} while (!str.equals("stop"));
```

This chunk is called by {BRReadLines.java}; see its first definition at "Reading Strings", page 45.

7.3 Writing Console Output

The methods

- print()
- println()

are defined by the class PrintStream (which is the type of object referenced by System.out). Remember, System.out is a byte stream, but is acceptable for simple program output. A character-based alternative is described in the next section.

Because PrintStream is an output stream (type byte) derived from OutputStream (an abstract byte stream class), it also implements the low-level method write(). Thus, write() can be used to write to the console. The simplest form of write() defined by PrintStream is here:

```
void write(int byteval)
```

This method writes the byte specified by *byteval*. Although *byteval* is declared as in integer, only the low-order eight bits are written.

Here is a short example that uses write() to output the character "A" followed by a newline to the screen:

```
//Demonstrate System.out.write()
class WriteDemo {
  public static void main (String[] args) {
   int b;
```

```
b = 'A';
System.out.write(b);
System.out.write('\n');
}
```

7.4 The PrintWriter Class

Using System.out to write to the console is probably best for debugging purposes or for sample programs. For real-world programs, the recommended method of writing to the console when using Java is through a PrintWriter stream. PrintWriter is one of the character-based classes. User a character-based class for console output makes internationalizing your program easier.

7.4.1 PrintWriter Constructors

PrintWriter defines several constructors. Here is one:

PrintWriter(OutputStream outStream, boolean flusingOn)

outputStream is an object of type OutputStream, and flushingOn controls whether Java flushes the output stream every time a println method is called. If flushingOn is true, flushing automatically takes place. If false, flushing is not automatic.

PrintWriter supports print() and println() methods. You can use these methods in the same way you used them with System.out. If an argument is not a simple type, the PrintWriter methods call the object's toString() method and then display the result.

Writing to the Console with a PrintWriter

To write to the console by using a PrintWriter, specify System.out for the output stream and automatic flushing.

```
PrintWriter pw = new PrintWriter(System.out, true);
```

7.4.2 Demonstration Using a PrintWriter for Console Output

```

This chunk is called by {PrinterWriterDemo.java}; see its first definition at "Demonstration Using a PrintWriter for Console Output", page 47.

7.4.2.2 PrintWriterDemo Printing To Console

```
<PrintWriterDemo Printing To Console> =
    pw.println("This is a string");
    int i = -7;
    pw.println(i);
    double d = 4.5e-7;
    pw.println(d);
```

This chunk is called by {PrinterWriterDemo.java}; see its first definition at "Demonstration Using a PrintWriter for Console Output", page 47.

7.4.3 PrintWriter Concluding Comments

There is nothing wrong with using System.out to write simple text output to the console. Using a PrintWriter makes your real-world applications easier to internationalize. There is no other adavantage gained by using a PrintWriter in the simple programs, however.

7.5 Reading and Writing Files

Java provides a number of classes and methods that allow you to read and write files. The purpose of this section is to introduce the basic techniques that read from and write to a file. Although byte streams are used, these techniques can be adapted to the character-based streams.

.....

7.5.1 FileInputStream and FileOutputStream

Two of the most often-used stream classes are:

- FileInputStream
- FileOutputStream

which create byte streams linked to files.

Open a File

To open a file, create an object of one of these clases, specifying the name of the file as an argument to the constructor. We will use the following constructors:

 $\label{lem:file_norm} File Input Stream (String \textit{fileName}) \ throws \ File Not Found Exception \\ File Output Stream (String \textit{fileName}) \ throws \ File Not Found Exception \\$

Note that when an output file is opened, any preexisting file by the same name is destroyed.

Close a File

When you are done with a file, you must close it. This is done by calling the close() method, which is implemented by both FileInputStream and FileOutputStream.

```
void close() throws IOException
```

Closing a file releases the system resources allocated to the file. Failure to close a file can result in "memory leaks" because of unused resources remaining allocated.

AutoClosable Interface

Beginning with JDK 7, the close() method is specified by the AutoCloseable interface in java.lang. AutoCloseable is inherited by the Closable interface in java.io. Both interfaces are implemented by the stream classes, including FileInputStream and FileOutputStream.

Try With Resources

There are two basic approaches you can use to close a file. The first is the traditional approach, in which close() is called explicitly when the file is no longer needed. This is the approach used by all versions of Java prior to JDK 7.

The second is to use the try-with-resources statement added by JDK 7, which automatically closes a file when it is no longer needed. In this approach, no explicit call to close() is executed.

Reading From A File

To read from a file, you can use a version of read() that is defined within FileInputStream. int read() throws IOException

Each time that it is called, it reads a single byte from the file and returns the byte as an integer value. read() returns -1 when an attempt is made to read at the end of the stream.

Writing to a File

To write to a file, you can use the write() method defined by FileOutputStream. Its simplest form is:

```
void write(int byteval throws IOException
```

This method writes the byte specified by *byteval* to the file. Although *byteval* is declared as an integer, only the low-order eight bits are written to th file.

7.5.2 Demonstration Reading From a File

The following program uses read() to input and display the contents of a file that contains ASCII test. The name of the file is specified as a command-line argument.

The following table lists called chunk definition points.

```

if (args.length != 1) {
    System.out.printli("Usage: ShowFile filename");
    return;
}

// Attempt to open the file

        do {
            i = fin.read();
            if (i != -1) System.out.print ((char) i);
        } while (i != -1);
    } catch (IOException e) {
        System.out.println("Error Reading File");
    }

This chunk is called by the following chunks:

```

```

7.5.2.6 close() Within finally Block

Although the preceding example closes the file stream after the file is read, there is a variation that is often useful. The variation is to call close() within a finally block. In this approach, all of the methods that access the file are contained within a try block, and the finally block is used to close the file. This way, no matter how the try block terminates, the file is closed.

One advantage to this approach in general is that if the code that accesses a file terminates because of some non-I/O related exception, the file is still closed by the finally block.

Here is how the try block that reads the file can be recode:

} while (i != -1);
} catch (IOException e) {
   System.out.println("Error Reading File.");
} finally {
   // Close the file on the way out of the block.
   try {
     fin.close();
} catch (IOException e) {
     System.out.println ("Error Closing File.");
}
```

This chunk is called by {ShowFileAlt.java}; see its first definition at "close() Within finally Block", page 52.

7.5.3 Demonstration Reading From a File with a Single try Block

Sometimes it's easier to wrap the portions of a program that open a file and access the file within a single try block (rather than separating the two) and then use a finally block to close the file.

Here is another way to write the ShowFile program:

```
{ShowFileSingleTry} ≡

<ShowFile Initial Comments>
<ShowFileSingleTry Additional Initial Comment>
<Import java.io>
class ShowFileSingleTry {
   public static void main (String[] args) {
     <ShowFile Instance Variable Declarations>
     <ShowFile Open a File>
     <ShowFileSingleTry Read a File>
   }
}
```

The following table lists called chunk definition points.

```
Chunk name

<Import java.io>

<ShowFile Instance Variable Declarations>
<ShowFile Open a File>
<ShowFileSingleTry Additional Initial Comment>
<ShowFileSingleTry Read a File>

See "ShowFileSingleTry Read a File>

First definition point
See "Import java.io", page 44.
See "ShowFile Initial Comments", page 50.
See "ShowFile Instance Variable Declarations", page 50.
See "ShowFile Open a File", page 51.
See "ShowFile SingleTry Additional Initial Comment", page 53.

See "ShowFileSingleTry Read a File", page 54.
```

7.5.3.1 ShowFile SingleTry Additional Initial Comment

```
<ShowFileSingleTry Additional Initial Comment> \equiv /* This variation wraps the code that opens and
```

```
accesses the file within a single try block.

The file is closed by the finally block.

*/
```

This chunk is called by {ShowFileSingleTry}; see its first definition at "Demonstration Reading From a File with a Single try Block", page 53.

7.5.3.2 ShowFileSingleTry Read a File

In this approach, fin is initialized to null. In the finally block, the file is closed only if fin is not null. This works because fin will be non-null only if the file is successfully opened. Thus, close() is not called if an exception occurs while opening the file.

<ShowFileSingleTry Read a File> \equiv

```
// The following code opens a file, reads characters until EOF
// is encountered, and then closes the file via a finally block.
try {
  fin = new FileInputStream(args[0]);
  do {
    i = fin.read();
    if (i != -1) System.out.print((char) i);
  } while (i != -1);
} catch (FileNotFoundException e) {
  System.out.println("File Not Found.");
} catch (IOException e) {
  System.out.println("An I/O Error Occurred");
} finally {
  // Close file in all cases
  try {
    if (fin != null) fin.close();
  } catch (IOException e) {
    System.out.println("Error Clsoing File");
  }
}
```

This chunk is called by {ShowFileSingleTry}; see its first definition at "Demonstration Reading From a File with a Single try Block", page 53.

More Compact Catch Code

It is possible to make the try/catch sequence a bit more compact. Because FileNotFoundException is a subclass of IOException, it need not be caught separately. Here is the sequence recoded to eliminate catching FileNotFoundException. In this case, the standard exception message, which describes the error, is displayed.

```
} catch (IOException e) {
   System.out.println("I/O Error: " + e);
} finally {
   try {
     if (fin != null) fin.close();
   } catch (IOException e) {
     System.out.println("Error Closing File");
   }
}
```

In this approach, any error, including an error opening the file, is simply handled by the single catch statement. This approach may not be appropriate in cases in which you want to deal separately with a failure to open a file, such as might be caused by a mistyped filename. In such a situation, you might want to prompt for the correct name before entering a try block that accesses the file.

The next example uses write() to copy a file.

7.5.4 Demonstration Writing to a File

This example uses write() to copy a file.

Notice that all potential I/O errors are handled in the programs by the use of exceptions. This differs from some computer languages that use error codes to report file errors. They enable Java to easily differentiate the end-of-file condition from file errors when input is being performed.

        return;
    }
```

This chunk is called by {CopyFile.java}; see its first definition at "Demonstration Writing to a File", page 55.

7.5.4.4 CopyFile Copy a File

Notice that there are two separate try blocks used when closing the files. This ensures that both files are closed, even if the call to fin.close() throws an exception.

```
<CopyFile Copy a File> \( \) // Copy a file
try {
    // Attempt to open the files
    fin = new FileInputStream(args[0]);
    fout = new FileOutputStream(args[1]);

    do {
        i = fin.read();
        if (i != -1) fout.write(i);
        } while (i != -1);
```

```
} catch (IOException e) {
    System.out.println("I/O Error: " + e);
} finally {
    try {
        if (fin != null) fin.close();
    } catch (IOException e2) {
        System.out.println("Error Closing Input File");
    }

    try {
        if (fout != null) fout.close();
    } catch (IOException e2) {
        System.out.println("Error Closing Output File");
    }
}
```

This chunk is called by {CopyFile.java}; see its first definition at "Demonstration Writing to a File", page 55.

7.6 Automatically Closing Files

JDK 7 added a feature that offers another way to manage resources, such as file streams, by automating the closing process. This feature, sometimes referred to as automatic resource management, or ARM for short, is based on an expanded version of the try statement. This form of try is called the try-with-resources statement. The principal advantage of automatic resource management is that it prevents situations in which a file (or other resource) is inadvertently not released after it is no longer needed.

Here is its general form:

```
try (resource-specification) {
  // use the resource
}
```

GeneralForm 7.1: General Form Automatic Resource Management

Typically, resource-specification is a statement that declares and initializes, such as a file stream. It consists of a variable declaration in which the variable is initialized with a reference to the object begin managed. When the try block ends, the resource is automatically released. In the case of a file, this means that the file is automatically closed. This form of try can also include catch and finally clauses. A resource declared in the try statement is implicitly final. This means that you can't assign to the resource after it has been created. The scope of the resource is limited to the try-with-resources statement.

Beginning with JDK 9, it is also possible for the resource specification of the try to consist of a variable that has been declared and initialized earlier in the program. However, that variable must be effectively final, which means that it has not been assigned a new value after being given its initial value.

AutoCloseable Interface

The try-with-resources statement can be used only with those resources that implement the AutoCloseable interface defined by java.lang. This interface defines the close() method. AutoCloseable is inherited by the Closeable interface in java.io. Both interfaces are implemented by the stream classes. Thus, try-with-resources can be used when working with streams, including file streams.

Multiple Resources

You can manage more than one resource within a single try statement. Simply separate each resource specification with a semicolon.

7.6.1 Demonstration of Automatically Closing a File

Here is a reworked verion of the ShowFile program using try-with-resources.

```

7.6.1.4 Open a File TryWR

Pay special attention to how the file is opened within the try statement. The resource-specification portion of the try declares a FileInputStream called fin, which is then assigned a reference to the file opened by its constructor. Therefore, here, the variable fin is local to the try block, being created when the try is entered. When the try is left, the stream associated with fin is automatically closed by an implicit call to close(). Since you don't call close() explicitly, you can't forget to close the file. This is a key advantage of using try-with-resources.

```
<ShowFileTryWR Open a File TryWR> \equiv /* The following code uses a try-with-resources statement to open
```

```
a file and then automatically close it when the try block is left. */
try (FileInputStream fin = new FileInputStream(args[0])) {
   do {
      i = fin.read();
      if (i != -1) System.out.print((char) i);
   } while (i != -1);
} catch (FileNotFoundException e) {
   System.out.println("File Not Found.");
} catch (IOException e) {

7.6.2.2 CopyFileMultTryWR Manage Two Files

Note how the input and output files are opened within the try block. After this block ends, both fin and fout will have been closed. This code is much shorter. The ability to streamline source code is a side-benefit of automatic resource management.

```

            i = fin.read();
            if (i != -1) fout.write(i);
        } while (i != -1);
    } catch (IOException e) {

9 Generics

Generics, introduced in J2SE 5.0, allows a type or method to operate on objects of various types while providing compile-time type safety. It adds compile-time type safety to the Collections Framework and eliminates the need of casting. In other words, generics allow you to abstract over types.

Through the use of generics, it is possible to create classes, interfaces, and methods that will work in a type-safe manner with various kinds of data. Many algorithms are logically the same no matter what type of data they are being applied to. For example, the mechanism that supports a stack is the same whether that stack is storing items of type Integer, String, Object, or Thread. With generics, you can define an algorithm once, independently of any specific type of data, and then apply that algorithm to a wide variety of data types without any additional effort.

Perhaps the one feature of Java that has been most significantly affected by generics is the *Collections Framework*. A *collection* is a group of objects. The Collections Framework defines several classes, such as lists and maps, that manage collections. The collection classes have always been able to work with any type of object. The benefit that generics adds is that the collection classes can now be used with complete type safety.

This chapter describes the syntax, theory, and use of generics. It also shows how generics provide type safety for some previously difficult cases.

9.1 Motivation for Generics

Code Fragment Without Generics

Here is a typical code fragment abstracting over types by using Object and type casting.

```
List myIntList = new LinkedList(); // 1
myIntList.add(new Integer(0)); // 2
Integer x = (Integer) myIntList.iterator().next(); // 3
```

The cast on line 3 is annoying, although essential. The compiler can guarantee only that an Object will be returned by the iterator. This therefore adds both clutter and the possibility of a run-time error.

Code Fragment with Generics

Generics allow a programmer to mark their intent to restrict a list to a particular data type. Here is a version of the same code that uses generics.

```
List<Integer> myIntList = new LinkedList<Integer>(); // 1'
myIntList.add(new Integer(0)); // 2'
Integer x = myIntList.iterator().next(); // 3'
```

In line 1, the type declaration for the variable myIntList specifies that it is to hold a List of Integers: 'List<Integer>'. List is a generic interface that takes a type parameter (Integer). The type parameter is also specified when creating the List object ('new LinkedList<Integer>()'). Also, the cast on line 3 is gone.

So has this just moved the clutter around, from a type cast to a type parameter? No, because this has given the compiler the ability to check the type correctness of the program

at compile-time. When we say that myIntList is declared with type List<Integer>, this tells us something about the variable myIntList, which holds true wherever and whenever it is used, and the compiler will guarantee it. In contrast, the cast tells us something the programmer thinks is true at a single point in the code.

The net effect, especially in large programs, is improved readability and robustness.

9.2 What Are Generics

The term generics means parameterized types. Parameterized types are important because they enable you to create classes, interfaces, and methods in which the type of data upon which they operate is specified as a parameter. Using generics, it is possible to create a single class, for example, that automatically works with different types of data. A class, interface, or method that operates on a parameterized type is called generic, as in generic class or generic method.

Java has always given the ability to create generalized classes, interfaces, and methods by operating through references of type Object. Generics added the type safety that was lacking. They also streamlined the process, because it is no longer necessary to explicitly employ casts to translate between Object and the type of data that is being operate upon. With generics, all casts are automatic and implicit.

9.3 A Simple Generics Example

The following program defines two classes. The first is the generic class Gen, and the second is GenDemo, which uses Gen.

```
{SimpleGenerics.java} ≡

< Class Gen>

< Class GenDemo>
```

The following table lists called chunk definition points.

Chunk name First definition point

< Class Gen> See "Class Gen¡T¿", page 65.

< Class GenDemo> See "Class GenDemo", page 66.

9.3.1 Class Gen<T>

This is a simple generic class. The class Gen is declared with a parameter of '<T>':

```
class Gen<T> {
```

'T' is the name of a *type parameter*. This name is used as a placeholder for the actual type that will be passed to **Gen** when an object is created. Thus, 'T' is used within **Gen** whenever the type parameter is needed.

Notice that 'T' is contained within '< >'. This syntax can be generalized. Whenever a type parameter is being declared, it is specified within angle brackets.

Because Gen uses a type parameter, Gen is a *generic class*, which is also called a *parameterized type*.

Outline of Class Gen<T>

Class Gen contains four parts:

- an instance variable declaration
- a constructor
- a method returning the instance variable
- a method describing the type of the instance variable

```
<Class Gen> ≡
    class Gen<T> {
        <Instance Variable ob of Type T>
        <Constructor taking parameter of Type T>
        <Method returning object of type T>
        <Method showing type of T>
}
```

This chunk is called by {SimpleGenerics.java}; see its first definition at "A Simple Generics Example", page 64.

The following table lists called chunk definition points.

Implementation of Class Gen<T>

'T' is used to declare an object called ob. 'T' is a placeholder for the actual type that will be specified when a Gen object is created. Thus, ob will be an object of the type passed to 'T'.

```
<Instance Variable ob of Type T> \(\text{T}\)
T ob; // declare an object of type T
```

This chunk is called by *Class Gen*; see its first definition at "Class Gen; T;", page 65.

The Constructor

Here is the constructor for Gen. Notice that its parameter, o, is of type 'T'. This means that the actual type of o is determined by the type passed to 'T' when a Gen object is created. Because both the parameter o and the member variable ob are of type 'T', they will both be the same actual type when a Gen object is created.

```
<Constructor taking parameter of Type T> =
   // Pass the constructor a reference to
   // an object of type T
   Gen (T o) {
     ob = o;
}
```

This chunk is called by *Class Gen*; see its first definition at "Class Gen;T;", page 65.

Instance Methods getob() and showType()

The type parameter 'T' can also be used to specify the return type of a method, as here in getob(). Because ob is also of type 'T', its type is compatible wih the return type specified by getob().

```
<Method returning object of type T> =
    // Return ob
    T getob() {
        return ob;
    }
```

This chunk is called by *Class Gen*; see its first definition at "Class Gen; T;", page 65.

The method showType() displays the type of 'T' by calling getName() on the Class object return by the call to getClass() on ob. The getClass() method is defined by Object and is thus a member of all class types. It returns a Class object that corresponds to the type of the class of the object on which it is called. Class defines the getName() method, which returns a string representation of the class name.

```
<Method showing type of T > =
    // Show type of T
    void showType() {
        System.out.println("Type of T is " + ob.getClass().getName();
    }
```

This chunk is called by *Class Gen*; see its first definition at "Class Gen; T;", page 65.

9.3.2 Class GenDemo

The GenDemo class demonstrates the generic Gen class.

But first, take note: The Java compiler does not actually create different versions of Gen, or of any other generic class. The compiler removes all generic type information, substituting the necessary casts, to make your code behave as if a specific version of Gen were created. There is really only one version of Gen that actually exists.

The process of removing generic type information is called *type erasure*.

GenDemo first creates a version of Gen for integers and calls the methods defined in Gen on it. It then does the same for a String object.

```
<Class GenDemo> =
    // Demonstrate the generic class
    class GenDemo {
        public static void main(String args[]) {
            <Create a Gen object for Integers>
            <Create a Gen object for Strings>
        }
    }
}
```

This chunk is called by {SimpleGenerics.java}; see its first definition at "A Simple Generics Example", page 64.

The following table lists called chunk definition points.

Chunk name	First definition point
<pre><create a="" for="" gen="" integers="" object=""></create></pre>	See "Implementation of Class GenDemo with Type Integer",
<pre><create a="" for="" gen="" object="" strings=""></create></pre>	page 67. See "Implementation of Class GenDemo with Type String", page 68.

9.3.2.1 Implementation of Class GenDemo with Type Integer

```
<Create a Gen object for Integers> ≡
     <Integer Type Parameter>
     <Reference to Integer Instance>
     <Show Type>
     <Get Value>
```

This chunk is called by *Class GenDemo*; see its first definition at "Class GenDemo", page 66. The following table lists called chunk definition points.

Chunk name	First definition point
<get value=""></get>	See "Implementation of Class GenDemo with Type Integer", page 68.
<integer parameter="" type=""></integer>	See "Implementation of Class GenDemo with Type Integer", page 67.
<reference instance="" integer="" to=""></reference>	See "Implementation of Class GenDemo with Type Integer", page 68.
<show type=""></show>	See "Implementation of Class GenDemo with Type Integer", page 68.

Integer Type Declaration

A reference to an Integer is declared in iOb. Here, the type 'Integer' is specified within the angle brackets after Gen. 'Integer' is a type argument that is passed to Gen's type parameter, 'T'. This effectively creates a version of Gen in which all references to 'T' are translated into references to 'Integer'. Thus, ob is of type 'Integer', and the return type of getob() is of type 'Integer'.

```
<Integer Type Parameter> =
Gen<Integer> iOb;
```

This chunk is called by *Create a Gen object for Integers>*; see its first definition at "Implementation of Class GenDemo with Type Integer", page 67.

Reference Assignment

The next line assigns to iOb a reference to an instance of an 'Integer' version of the Gen class. When the Gen constructor is called, the type argument 'Integer' is also specified. This is because the type of the object (in this case iOb to which the reference is being assigned is of type Gen<Integer>. Thus, the reference returned by new must also be of type Gen<Integer>. If it isn't, a compile-time error will result. This type checking is one of the main benefits of generics because it ensures type safety.

Notice the use of autoboxing to encapsulate the value 88 within an Integer object.

```
<Reference to Integer Instance> \equiv iOb = new Gen<Integer>(88);
```

This chunk is called by *Create a Gen object for Integers*>; see its first definition at "Implementation of Class GenDemo with Type Integer", page 67.

The automatic autoboxing could have been written explicitly, like so:

```
iOb = new Gen<Integer>(Integer.valueOf(88));
```

but there would be no value to doing it that way.

Showing the Reference's Type

The program then uses Gen's instance method to show the type of ob, which is an 'Integer' in this case.

```
<Show\ Type> \equiv iOb.showType();
```

This chunk is called by *Create a Gen object for Integers*>; see its first definition at "Implementation of Class GenDemo with Type Integer", page 67.

Showing the Reference's Value

The program now obtains the value of ob by assiging ob to an 'int' variable. The return type of getob() is 'Integer', which unboxes into 'int' when assigned to an 'int' variable (v). There is no need to cast the return type of getob() to 'Integer'.

```
<Get Value> \( \)
int v = iOb.getob();
System.out.println("value: " + v);
System.out.println();
```

This chunk is called by *Create a Gen object for Integers*>; see its first definition at "Implementation of Class GenDemo with Type Integer", page 67.

9.3.2.2 Implementation of Class GenDemo with Type String

```
<Create a Gen object for Strings> \( // \) Create a Gen object for Strings.
Gen<String> str0b = new Gen<String>("Generics Test");

// Show the type of data used by str0b
str0b.showType();

// Get the value of str0b. Again, notice
// that no cast is needed.
String str = str0b.getob();
System.out.println("value: " + str);
```

This chunk is called by *Class GenDemo*; see its first definition at "Class GenDemo", page 66.

9.4 Notes About Generics

9.4.1 Generics Work Only with Reference Types

When declaring an instance of a generic type, the type argument passed to the type parameter must be a reference type. It cannot be a primitive type, such as 'int' or 'char'.

You can use the type wrappers to encapsulate a primitive type. Java's autoboxing and auto-unboxing mechanism makes the use of the type wrapper transparent.

9.4.2 Generic Types Differ Based on their Type Arguments

A reference of one specific version of a generic type is not type-compatible with another version of the same generic type. In other words, the following line of code is an error and will not compile:

```
iOb = strOb; // Gen<Integer> != Gen<String>
```

These are references to different types because their type arguments differ.

9.4.3 Generics and Subtyping

Is the following legal?

```
List<String> ls = new ArrayList<String>(); // 1
List<Object> lo = ls; // 2
```

Line 1 is legal. What about line 2? This boils down to the question: "is a List of String a List of Object." Most people instinctively answer, "Sure!"

Now look at these lines:

```
lo.add(new Object()); // 3
String s = ls.get(0); // 4: Attempts to assign an Object to a String!
```

Here we've aliased 1s and 1o. Accessing 1s, a list of String, through the alias 1o, we can insert arbitrary objects into it. As a result 1s does not hold just Strings anymore, and when we try and get something out of it, we get a rude surprise.

The Java compiler will prevent this from happening of course. Line 2 will cause a compile time error.

The take-away is that, if Foo is a subtype (subclass or subinterface) of Bar, and G is some generic type declaration, it is not the case that G<Foo> is a subtype of G<Bar>.

9.4.4 How Generics Improve Type Safety

Generics automatically ensure the type safety of all operations involving a generic class, such as Gen. They eliminate the need for the coder to enter cases and to type-check code by hand.

9.5 A Generic Class with Two Type Parameters

You can declare more than one type parameter in a generic type. To specify two or more type parameters, use a comma-separated list. When an object is created, the same number of type arguments must be passed as there are type parameters. The type arguments can be the same or different.

9.5.1 Example of Code with Two Type Parameters

```
\{ {\tt TwoTypeParameters.java} \} \equiv $$ < Class TwoGen > $$ < Class SimpGen > $$
```

Class Declaration

Notice how TwoGen is declared. It specifies two type parameters: 'T' and 'V', separated by a comma. Because it has two type parameters, two type arguments must be passed to TwoGen when an object is created.

9.5.1.2 Class SimpGen

Two type arguments must be supplied to the constructor. In this case, the two type parameters are 'Integer' and 'String'.

```
<Class SimpGen> \( \)
    class SimpGen {
        public static void main(String args[]) {
            TwoGen<Integer, String> tgObj =
                new TwoGen<Integer, String>(88, "Generics");

            // Show the types
            tgObj.showTypes();

            // Obtain and show values
            int v = tgObj.getob1();
            System.out.println("value: " + v);

            String str = thObj.getob2();
            System.out.println("value: " + str);
            }
        }
}
```

This chunk is called by {TwoTypeParameters.java}; see its first definition at "Example of Code with Two Type Parameters", page 70.

9.6 The General Form of a Generic Class

new class-name < type-arg-list > (cons-arg-list);

The generics syntax shown above can be generalized. Here is the syntax for declaring a generic class:

```
class class-name<type-param-list> { . . .

Here is the full syntax for declaring a reference to a generic class and instance creation:

class-name<type-arg-list> var-name =
```

GeneralForm 9.1: General Form for Declaring and Creating a Reference to a Generic Class

9.7 Bounded Types

Sometimes it can be useful to limit the types that can be passed to a type parameter. Java provides bounded types. When specifying a type parameter, you can create an upper bound that declares the superclass from which all type arguments must be derived. This is accomplished through the use of an extends clause when specifying the type parameter:

```
< T extends superclass>
```

This specifies that T can only be replaced by superclass or subclasses of superclass. Thus, superclass defines an inclusive, upper limit.

Interface Type as a Bound

In addition to using a class type as a bound, you can also use an interface type. In fact, youi can specify multiple interfaces as bounds. Furthermore, a bound can include both a class type and one or more interfaces. In this case, the class type must be specified first. When a bound includes an interface type, only type arguments that implement that interface are legal.

When specifying a bound that has a class and an interface, or multiple interfaces, use the & operator to connnect them.

```
class Gen<T extends MyClass & MyInterface> { ...
```

Any type argument passed to 'T' must be a subclass of MyClass and implement MyInterface.

9.8 Using Wildcard Arguments

9.8.1 Wildcard Motivation

Consider the problem of writing a routine that prints out all the elements in a collection. Here's how you might write it in an older version of the language (i.e., a pre-5.0 release):

```
void printCollection(Collection c) {
    Iterator i = c.iterator();
    for (k = 0; k < c.size(); k++) {
        System.out.println(i.next());
    }
}</pre>
```

And here is a naive attempt at writing it using generics (and the new for loop syntax):

```
for (Object e : c) {
        System.out.println(e);
}
```

The problem is that this new version is much less useful than the old one. Whereas the old code could be called with any kind of collection as a parameter, the new code only takes Collection<Object>, which, as we've just demonstrated, is *not* a supertype of all kinds of collections!

So what is the supertype of all kinds of collections? It's written <code>Collection<?></code> (pronounced collection of unknown), that is, a collection whose element type matches anything. It's called a wildcard type. We can write:

```
void printCollection(Collection<?> c) {
    for (Object e : c) {
        System.out.println(e);
    }
}
```

and now, we can call it with any type of collection. Notice that inside printCollection(), we can still read elements from c and give them type Object. This is always safe, since whatever the actual type of the collection, it does contain objects. It isn't safe to add arbitrary objects to it however:

```
Collection<?> c = new ArrayList<String>();
c.add(new Object()); // Compile time error
```

Since we don't know what the element type of c stands for, we cannot add objects to it. The add() method takes arguments of type E, the element type of the collection. When the actual type parameter is ?, it stands for some unknown type. Any parameter we pass to add would have to be a subtype of this unknown type. Since we don't know what type that is, we cannot pass anything in. The sole exception is null, which is a member of every type.

On the other hand, given a List<?>, we can call get() and make use of the result. The result type is an unknown type, but we always know that it is an object. It is therefore safe to assign the result of get() to a variable of type Object or pass it as a parameter where the type Object is expected.

9.8.2 Wildcard Syntax

Sometimes type safety can get in the way of perfectly acceptable constructs. In such cases, there is a *wildcard* argument that can be used. The wildcard argument is specified by the ?, and it represents an unknown type. It would be used in place of a type parameter, for example:

```
boolean sameAvg(Stats<?> ob) {
  if(average() == ob.average())
    return true;
  return false;
}
```

Here, 'Stats<?>' matches any Stats object (Integer, Double), allowing any two Stats objects to have their averages compared. The wildcard does not affect what type of Stats object can be created. That is governed by the extends clause in the Stats declaration. The wildcard simply matches any *valid* Stats object.

9.8.3 Bounded Wildcards

Wildcard arguments can be bounded in much the same way that a type parameter can be bounded (the *bounded wildcard argument*. A bounded wildcard is especially important when you are creating a generic type that will operate on a class hierarchy.

A bounded wildcard specifies either an upper bound or a lower bound for the type argument. This enables you to restrict the types of objects upon which a method will operate.

Upper Bounded Wildcard

The most common bounded wildcard is the upper bound, which is created using an extends clause. In general, to establish an upper bound for a wildcard, use the following type of wildcard expression:

<? extends *superclass*>

GeneralForm 9.2: General Form of Upper Bounded Wildcard Syntax

where *superclass* is the name of the class that serves as the upper bound. This is an inclusive clause.

Lower Bounded Wildcard

You can also specify a lower bound for a wildcard by adding a **super** clause to a wildcard declaration. Here is its general form:

<? super subclass>

GeneralForm 9.3: General Form of Lower Bounded Wildcard Syntax

Only classes that are superclasses of *subclass* are acceptable arguments

9.9 Creating a Generic Method

It is possible to declare a generic method that uses one or more type parameters of its own. It is also possible to create a generic method that is enclosed within a non-generic class.

Generalized Form

```
< type-param-list > ret-type meth-name ( param-list ) { . . . }
```

GeneralForm 9.4: General Form for Declaring a Generic Method

9.9.1 Example of Generic Method

The following program declares a non-generic class called GenMethDemo and a static generic method within that class called isIn(). The isIn() method determines if an object is a member of an array. It can be used with any type of object and array as long as the array contains objects that are compatible with the type of the object being sought.

The following table lists called chunk definition points.

```
Chunk name First definition point 

<GenMethDemo Main> See "GenMethDemo Main", page 75. 
<Static Method isIn> See "Method isIn()", page 75.
```

9.9.1.1 Method isIn()

The **type parameters** are declared *before* the return type of the method.

```
<Static Method isIn> =
    static <T extends Comparable<T>, V extends T> boolean isIn(T x, V[] y) {
    for (int i = 0; i < y.length; i++)
        if (x.equals(y[i]) return true;
    return false;
}</pre>
```

This chunk is called by {GenMethDemo.java}; see its first definition at "Example of Generic Method", page 75.

The type T is **upper-bounded** by the Comparable interface, which must be of the same type as T. Likewise, the second type, V, is also **upper-bounded** by T. Thus, V must be either the same type as T or a subclass of T. This relationship enforces that isIn() can be called only with arguments that are compatible with each other.

While isIn() is static in this case, generic methods can be either static or non-static; there is no restriction in this regard.

Explicitly Including Type Arguments

There is generally no need to specify type arguments when calling this method from within the main routine. This is because the type arguments are automatically discerned, and the types of T and V are adjusted accordingly.

Although type inference will be sufficient for most generic method calls, you can explicitly specify the type argument if needed. For example, here is how the first call to <code>isIn()</code> looks when the type arguments are specified:

```
GenMethDemo.<Integer, Integer>isIn(2, nums)
```

9.9.1.2 GenMethDemo Main

```
<GenMethDemo Main> =
    public static void main(String args[]) {
    // call isIn() with Integer type
```

```
Integer nums[] = { 1, 2, 3, 4, 5 };
if ( isIn(2, nums) )
  System.out.println("2 is in nums");
if (@isIn(7, nums))
  System.out.println("7 is not in nums");
System.out.println();
// call isIn() with String type
String strs[] = { "one", "two", "three", "four", "five" };
if ( isIn("two", strs))
  System.out.println("two is in strs");
if (!isIn("seven", strs))
  System.out.println("seven is not in strs");
// call isIn() with mixed types
// WILL NOT COMPILE! TYPES MUST BE COMPATIBLE
// if ( isIn("two", nums))
      System.out.println("two is in nums");
```

This chunk is called by {GenMethDemo.java}; see its first definition at "Example of Generic Method", page 75.

9.10 Generic Constructors

It is possible for constructors to be generic, even if their class is not (see "Class Gen;T;", page 65). The syntax is the same (type parameters come first).

< type-param-list> constructor-name (param-list) { . . .

10 Enumerations

Enumerations were added by JDK 5. In earlier versions of Java, enumerations were implemented using final variables.

An enumeration is a list of named constants that define a new data type and its legal values. In other words, an enumeration defines a class type. An enumeration object can only hold values that were declared in the list. Other values are not allowed. An enumeration allows the programmer to define a set of values that a data type can legally have.

By making enumerations classes, the capabilities of the enumeration are greatly expanded. An enumeration can have:

- constructors
- methods
- instance variables

10.1 Enumeration Basics

An enumeration is created using the enum keyword.

```
enum Apple {
     Jonathon, GoldenDel, RedDel, Winesap, Cortland
}
```

enumeration constants

The enum constants 'Jonathon', 'GoldenDel', etc. are called enumeration constants. The enumeration constants are declared as 'public static final' members of the enum. Their type is the type of the enumeration in which they are declared. These constants are called self-typed, in which "self" refers to the enclosing enumeration.

enumeration objects

You can create a variable of an enumeration type. You do not instantiate an enum using new. Rather, you declare an enum variable like you do for primitive types: 'Apple ap'. Now, the variable ap can only hold values of type 'Apple'.

```
Apple ap;
ap = Apple.RedDel;
The enum type (i.e., Apple) must be part of the expression.
```

Comparing for Equality; Switch

Two enumeration constants can be compared for equality using the == relational operator. Furthermore, an enumneration value can be used to control a switch statement. The enum prefix (type) is not required for switch.

```
switch(ap) {
  case Jonathon: ...
  case Winesap: ...
}
```

Printing Enum Types

When an enumeration object is printed, its name is output (without the enum type): 'System.out.println(ap)' would produce 'RedDel'.

10.2 Enum Methods values() and valueOf()

All enumerations inherit two methods:

```
public static enum-type[]
values ()
[Method on Enum]
```

The values() method returns an array that contains a list of the enumeration constants.

```
public static enum-type
valueOf (String str)
[Method on Enum]
```

The valueOf() method returns the enumeration constant whose value corresponds to the string passed in str.

Examples using values() and valueOf() Methods

'Apple allapples[] = Apple.values();' is an example of using the values() method to populate an array with enumeration constants.

```
for(Apple a : Apple.values()) {
   System.out.println(a);
}
```

is an example of iterating directly on the values() method.

```
Apple ap;
ap = Apple.valueOf("Winesap");
System.out.println("ap contains " + ap);
```

is an example of using the valueOf() method to obtain the enumeration constant corresponding to the value of a string.

10.3 Java Enumerations are Class Types

A Java enumeration is a class type. That is, enum defines a class, which has much the same capabilities as other classes. An enumeration can be given constructors, instance variables, and methods. It can even implement interfaces. Each enumeration constant is an object of its enumeration type. When an enumeration is given a constructor, the constructor is called when each enumeration constant is created. Also, each enumeration constant has its own copy of any instance variables defined by the enumeration.

```
enum Apple {
   Jonathon(10), GoldenDel(9), RedDel(12), Winesap(15), Cortland(8);
   private int price;
   Apple(int p) { price = p; }
   int getPrice() { return price; }
}
class EnumDemo {
```

```
public static void main (String[] args) {
   Apple ap;
}
```

In this example, the enumeration 'Apple' is given an instance variable price, a constructor, and an instance method 'getPrice()'. When the variable 'ap' is declared in 'main()', the constructor for 'Apple' is called once for each constant that is specified. The arguments to the constructor are placed in parentheses after the name of each constant. Thereafter, each enumeration constant has its own copy of 'price', which can be obtained by calling the instance method 'getPrice()'. In addition, there can be multiple overloaded constructors just as for any other class.

Restrictions on Enums

- An enumeration cannot inherit another class.
- An enum cannot be a superclass (enum cannot be extended).

The key is to remember that each enumeration constant is an object of the class in which it is defined.

10.4 Enumerations Inherit Enum

All enumerations automatically inherit from one superclass: java.lang.Enum. This class defines several methods that are available for use by all enumerations.

```
ordinal() and compareTo()
```

```
final int [Method on Enum] ordinal ()
```

The ordinal() method returns a value that indicates an enumeration constant's position in the list of constants, called its *ordinal value*. In other words, calling ordinal() returns the ordinal value of the invoking constant (zero indexed).

```
final int [Method on Enum] compareTo (enum-type e)
```

The ordinal values of two constants can be compared using the compareTo() method. Both the invoking constant and e must be of the same enumeration enum-type. This method returns a negative value, a zero, or a positive value depending on whether the invoking constant's ordinal value is less than, equal to, or greater than the passed-in enumeration constant's ordinal value.

Compare for equality an invoking enum constant with a referenced enum constant.

An invoking enum constant can compare for equality itself with any other object by using equals() or, equivalently, ==, which overrides the equals() method defined in Object. equals() will return true only if both objects refer to the same constant within the same enumeration. (In other words, equals does not just compare ordinal values in general.)

12 java.lang

Classes and interfaces defined by java.lang, which is automatically imported into all programs. Contains classes and interfaces that are fundamental to all of Java programming. Beginning with JDK 9, all of java.lang is part of the java.base module.

java.lang includes the following classes

- Boolean
- Byte
- Character
 - Character.Subset
 - Character.UnicodeBlock
- Class
- ClassLoader
- ClassValue
- Compiler
- Double
- Enum
- Float
- InheritableThreadLocal

12.1 Primitive Type Wrappers

Java uses primitive types for 'int', 'char', etc. for performance reasons. These primitives are not part of the object hierarchy; they are passed by-value, not by reference. Sometimes you may need to create an object representation for a primitive type. To store a primitive in a class, you need to wrap the primitive type in a class.

Java provides classes that correspond to each of the primitive types. These classes encapsulate or *wrap* the primitive types within a class. They are commonly referred to as *type wrappers*.

15 Input/Output — java.io

This chapter explores <code>java.io</code>, which provides support for I/O operations. Data is retrieved from an <code>input</code> source. The results of a program are sent to an <code>output</code> destination. In Java, these sources or destinations are defined very broadly. Although physically different, these devices are all handled by the same abstraction: the <code>stream</code>. An I/O stream is a logical entity that either produces or consumes information. An I/O stream is linked to a physical device by the Java I/O system. All I/O streams behave in the same manner, even if the physical devices they are linked to differ.

Beginning with version 1.4, a second I/O system was added to Java, called NIO (which meant New I/O). NIO is packaged in java.nio and its subpackages. The NIO is described in Chapter 16 "NIO", page 115.

15.1 I/O Classes and Interfaces

15.1.1 I/O Classes Defined by java.io

- BufferedInputStream / BufferedOutputStream
- BufferedReader / Buffered Writer
- ByteArrayInputStream / ByteArrayOutputStream
- CharArrayReader / CharArrayWriter
- Console
- DataInputStream / DataOutputStream
- File
- FileDescriptor
- FileInputStream / FileOutputStream

15.2 File

The File class does not operate on streams. It deals directly with files and the file system. The File class does not specify how information is retrieved from or stored in files; rather, it describes the properties of a file itself. A File object is used to obtain or manipulate the information associated with a disk file, such as the permissions, time, date, and directory path, and to navigate subdirectory hierarchies.¹

Files and Directories in Java

Files are a primary source and destination for data within programs. Files are a central resource for storing persistent and shared information. A directory in Java is treated simply as a File with one additional property — a list of filenames that can be examined by the list() method.

Constructors Used to Create File Objects

- File(String directoryPath)
- File(String directoryPath, String filename)
- File(File dirObj, String filename)
- File(URI *uriObj*)

¹ The Path interface and Files class, part of the NIO system, offer a powerful alternative to File. See Chapter 16 "NIO", page 115.

dirObj is a File object that specifies a directory, while uriObj is a URI object that describes a file.

Examples Creating Files and Directories

The following example creates three files. The first File object is constructed with a directory path as the only argument. The second includes two arguments — the path and the filename. The third includes the file path assigned to f1 and a filename; f3 refers to the same file as f2.

```
File f1 = new File("/");
File f2 = new File("/", "autoexec.bat");
File f3 = new File(f1, "autoexec.bat");
```

15.2.1 File Methods

File defines many methods that obtain the standard properties of a File object.

```
getName()
            returns the name of the file
getParent()
            returns the name of the parent directory
getPath()
getAbsolutePath()
           returns the path
exists() returns true if the file exists, false if it does not
canWrite()
canRead()
            returns whether the file is writeable/readable
isDirectory()
            returns whether the file is a directory
           returns whether the file is a regular file (true) or a non-file (false) such as
            directory, device drivers, named pipes, etc.
isAbsolute()
            returns whether the file is an absolute path (true) or a relative path (false)
lastModified()
            returns the modification date and time
          returns the file's size
length()
   Table 15.1: File Property Methods
```

15.2.2 File Utility Methods

renameTo()

boolean renameTo(File newName); returns true upon success or false if the file cannot be renamed

delete() boolean delete(); deletes a file or directory (if the directory is empty); returns true if it successfully deletes or false if the file or directory cannot be removed;

deleteOnExit()

removes the file associated with the invoking object when the Java Virtual Machines terminates

getFreeSpace()

returns the number of free bytes of storage (as a long) available on the partition associated with the invoking object

getTotalSpace()

returns the stoarage capacity (as a long) of the partition associated with the invoking object

getUsableSpace()

returns the number of usable free bytes of storage (as a long) available on the partition associated with the invoking object

isHidden()

returns true if the invoking file is hidden, or false otherwise

setLastModifiedTime()

sets the time stamp on the invoking file to that specified by the argument (long millisec), which is the number of milliseconds from January 1, 1970, UTC

setReadOnly()

sets the invoking to read-only; returns true on success

readable()

writeable()

executable()

compareTo()

because File implements the Comparable interface

toPath() returns a Path object that represents the file encapsulated by the invoking File object; (in other words, toPath() converts a File into a Path);²

mkdir()

mkdirs() the first creates a directory, returning true on success and false on failure; use the second to create a directory for which no path exists; it creates both a directory and all the parents of the directory;

Table 15.2: File Utility Methods

² toPath() forms a bridge between the older File class and the newer Path interface; See Chapter 16 "NIO", page 115.

15.2.3 Directories

A directory is a File that contains a list of other files and directories. When you create a File object that is a directory, the isDirectory() method will return true. In this case, you can call list() on that object to extract the list of other files and directories inside. It has two forms. Here is the more general form:

```
String[]
list ()
    list() is used to extract the list of other files and directories inside the calling File
    object
```

15.2.4 Using list() to Examine Directory Contents

This program illustrates how to use list() to examine the contents of a directory.

The following table lists called chunk definition points.

15.2.4.1 Import java.io.File

```
<Import java.io.File> ≡
import java.io.File;
```

This chunk is called by {DirList.java}; see its first definition at "Using list() to Examine Directory Contents", page 93.

15.2.4.2 DirList Instance Variable Declarations

```
<DirList Instance Variable Declarations> ≡
    <DirList Obtain Directory From Command-Line Args>
    String dirname = args[0];
    File f1 = new File(dirname);
```

This chunk is called by {DirList.java}; see its first definition at "Using list() to Examine Directory Contents", page 93.

The called chunk *OirList Obtain Directory From Command-Line Args* is first defined at "DirList Obtain Directory From Command-Line Args", page 94.

15.2.4.3 DirList Examine Directory Contents

```
<DirList Examine Directory Contents> \(\equiv \)
if (f1.isDirectory()) {
    System.out.println("Directory of " + dirname);

String[] s = f1.list();

<DirList Examine Directory Contents For-Loop>
} else {
    System.out.println(dirname + " is not a directory");
}
```

This chunk is called by {DirList.java}; see its first definition at "Using list() to Examine Directory Contents", page 93.

The called chunk *Directory Contents For-Loop* is first defined at "Examine Directory Contents For-Loop", page 94.

15.2.4.4 Examine Directory Contents For-Loop

```
<DirList Examine Directory Contents For-Loop> =
  for (int i = 0; i < s.length; i++) {
    File f = new File(dirname + "/" + s[i]);

  if (f.isDirectory()) {
    System.out.println(s[i] + " is a directory");
    } else {
    System.out.println(s[i] + " is a file");
    }
}</pre>
```

This chunk is called by *DirList Examine Directory Contents*; see its first definition at "DirList Examine Directory Contents", page 94.

15.2.4.5 DirList Obtain Directory From Command-Line Args

```
<DirList Obtain Directory From Command-Line Args> =
   if (args.length != 1) {
      System.out.println("Usage: java DirList <directory>");
      return;
   }
```

This chunk is called by the following chunks:

```
Chunk name First definition point
<DirList Instance Variable Declarations", page 93.
tions>

{DirListOnly} See "Example Program Using FilenameFilter Interface", page 96.
```

15.2.5 Using FilenameFilter

You can limit the number of files returned by the list() method to include only those files that match a certain filename pattern, or filter. To do this, use a second form of list:

```
String[] [Method on File]
```

list (FilenameFilter FFObj)

Returns an array of String filenames found in the directory named by the calling File object

GeneralForm 15.2: Obtaining a filtered list of files in a directory

Here, FFObj is an object of a class that implements the FilenameFilter interface. This interface defines a single method, accept(), which is called once for each file in a list. It's general form is given here:

```
boolean [Method on FilenameFilter] accept (File directory, String filename)
```

The accept() method returns true for files in the directory specified by the directory that should be included in the list (that is, those that match the filename argument) and returns false for those files that should be excluded.

GeneralForm 15.3: accept() Form to be used with list()

15.2.6 Example Program Using FilenameFilter Interface

The OnlyExt class implements FilenameFilter by defining an accept() method, which will be used by a variation of the preceding program listing the contents of a directory to filter the directory listing.

OnlyExt Class

This chunk is called by {DirListOnly}; see its first definition at "Example Program Using FilenameFilter Interface", page 96.

15.2.6.2 DirListOnly FilenameFilter Object List

Recall the corresophding line in the DirList program: See Section 15.2.4.3 "DirList Examine Directory Contents", page 94.

```
<DirListOnly FilenameFilter Object List> =
String[] s = f1.list(only);
```

This chunk is called by {DirListOnly}; see its first definition at "Example Program Using FilenameFilter Interface", page 96.

15.2.6.3 DirListOnly Print List

This chunk is called by {OnlyExt.java}; see its first definition at "Example Program Using FilenameFilter Interface", page 95.

15.2.7 listFiles() Alternative

There is a variation to the list() method, called listFiles(), that might be useful.

```
File[] [Method on File]
listFiles ()
File[] [Method on File]
listFiles (FilenameFilter FF0jb)
File[] [Method on File]
listFiles (FileFilter F0jb)
```

These methods return the

These methods return the file list as an array of File objects instead of Strings. The first method returns all files, and the second returns those files that satisfy the specified FilenameFilter. The third version of listFiles() returns those files with path names that satisfy the specified FileFilter. FileFilter defines only a single method, accept(), which is called once for each file in a list. Its general form is shown below (see GeneralForm 15.5).

GeneralForm 15.4: File.listFiles() Form

FileFilter.accept()

boolean [Method on FileFilter]

accept (File path)

Called once for each file in a list; it returns **true** for files that should be included in the list (that is, those that match the *path* argument) and **false** for those that should be excluded.

GeneralForm 15.5: FileFilter.accept() Method

15.2.8 Creating Directories

- boolean mkdir()
- boolen mkdirs()

15.3 The AutoCloseable, Closeable, and Flushable Interfaces

15.4 I/O Exceptions

IOException and FileNotFoundException

Two exceptions play an important role in I/O handling. The first is IOException. If an I/O error occurs, an IOException is thrown. In many cases, if a file cannot be opened, a FileNotFoundException is thrown. FileNotFoundException is a subclass of IOException, so both can be caught with a single catch that catches IOException. You might find it useful to catch each exception separately.

SecurityException

SecurityException

Another exception class that could occur during I/O is SecurityException. In situations in which a security manager is present, several of the file classes will throw a

SecurityException if a security violation occurs when attempting to open a file. By default, application run via java do not use a security manager. Other applications could generate a SecurityException, which will need to be handled.

15.5 Two Ways to Close a Stream

In general, a stream must be closed when it is no longer needed. Failure to do so can lead to memory leaks and resource starvation.

Traditional Method with close() in finally

Beginning with JDK 7, there are two basic ways in which you can close a stream. The first is to explicitly call close() on the stream. This is the traditional approach that has been used since the original release of Java. With this approach, close() is typically called within a finally block.

```
try {
  open and access file . . .
} catch (IOException) {
  handle IOException . . .
} finally {
  close the file . . .
}
```

GeneralForm 15.6: Simplified skeleton for traditional approach to close a stream

try-with-resources Statement

The second approach to closing a stream is to automate the process by using the try-with-resources statement added by JDK 7. The try-with-resources is an enhanced form of try with the following form:

```
try (resource-specification) {
  use the resource . . .
}
```

GeneralForm 15.7: Closing a file using try-with-resources Statement

Typically, resource-specification is a statement or statements that declare and initialize a resource, such as a file or other stream-related resource. It consists of a variable declaration in which the variable is initialized with a reference to the object being managed. When the try block ends, the resource is automatically released. In the case of a file, the file is automatically closed (there is no need to call close().

try-with-resources Under JDK 9

Beginning with JDK 9, it is also possible for the resource specification of the try to consist of a variable that has been declared and initialized earlier in the program. However, that variable must be effectively final, which means that it has not been assigned a new value after being given its initial value.

Here are three key points about try-with-resources statement:

• Resources must be objects of classes the implement AutoCloseable interface

- A resource declared in try is *implicitly* final, while a resource declared outside the try must be *effectively* final.
- More than one resource can be handled by separating each declaration with a semicolon.

Principal Advantages to using try-with-resources

A principal advantage of try-with-resources is that the resource is closed automatically when the try block ends. Thus, it is not possible to forget to close a stream. Another advantage is that the try-with-resources approach typically results in shorter, clear, easier-to-maintain source code.

15.6 The Stream Classes

Java's stream-based I/O is built upon four abstract classes:

- Byte Streams
 - InputStream
 - OutputStream
- Character Streams
 - Reader
 - Writer

The top-level classes define the basic functionality common to all stream classes. In general, you should use the character stream classes when working with characters or strings and use the byte stream classes when working with bytes or other binary objects.

15.7 The Byte Streams

The byte stream classes provide an environment for handling byte-oriented I/O. A byte stream can be used with any type of object, including binary data. The byte streams are topped by InputStream and OutputStream.

15.7.1 InputStream

InputStream is an abstract class that defines Java's model of streaming byte input. It implements the AutoCloseable and Closeable interfaces. Most of the methods in this class will throw an IOException when an I/O error occurs.³

³ The exceptions are mark() and markSupported().

15.7.1.1 InputStream Methods

int available()

Returns the number of bytes of input currently available for reading

void close()

Closes the input source. Further read attempts will generate an IOException.

void mark(int numBytes)

Places a mark at the current point in the input stream that will remain valid until *numBytes* bytes are read.

boolean markSupported()

Returns true if mark() / reset() are supported by the invoking stream.

int read() Returns an integer representation of the next available byte of input. -1 is returned when an attempt is made to read at the end of the stream.

int read(byte buffere//)

Attempts to read up to buffer.length bytes into buffer and returns the actual number of bytes that were successfully read. -1 is returned when an attempt is made to read at the end of the stream.

int read(byte buffer/), int offset, int numBytes)

Attempts to read up to *numBytes* bytes into *buffer* starting at *buffer*[offset], returning the number of bytes successfully read. -1 is returned when an attempt is made to read at the end of the stream.

byte[] readAllBytes()

Beginning at the current position, reads to the end of the stream, returning a byte array that holds the input. (Added by JDK 9.)

int readNBytes(byte buffer//, int offset, int numBytes)

Attempts to read up to *numBytes* bytes into *buffer* starting at *buffer*[offset], returning the number of types successfully read. (Added by JDK 9.)

void reset()

Resets the input pointer to the previously set mark.

long skip(long numBytes)

Ignores (that is, skips) numBytes bytes of input, returning the number of bytes actually ignored.

long transferTo(OutputStream strm)

Copies the bytes in teh invoking stream into *strm*, returning the number of bytes copies. (Added by JDK 9.)

Table 15.3: The Methods Defined by InputStream

15.7.2 OutputStream

OutputStream is an abstract class that defines streaming byte output. It implements AutoCloseable, Closeable, and Flushable interfaces. Most of the methods defined by this class return void and throw an IOException in the case of I/O errors.

15.7.2.1 OutputStream Methods

void close()

Closes the output stream. Further write attempts will generate an IOException.

void flush()

Finalizes the output state so that any buffers are cleared (it flushes the output buffers).

void write(int b)

Writes a single byte to an output stream. Note that the parameter is an int, which allows you to call write() with an expression without having to cast it back to byte.

void write(byte buffer//)

Writes a complete array of bytes to an output stream.

void write(byte buffer//, int offset, int numBytes)

Writes a subrange of numBytes bytes from the array buffer, beginning at buffer[offset].

Table 15.4: The Methods Defined by OutputStream

15.7.3 FileInputStream

The FileInputStream class creates an InputStream that you can use to read bytes from a file. Two commonly used constructors are:

FileInputStream(String filePath)

FileInputStream(File fileObj)

Either can throw a FileNotFoundException.

15.7.4 FileOutputStream

15.7.5 ByteArrayInputStream

15.7.6 ByteArrayOutputStream

15.7.7 Filtered Byte Streams

Filtered streams are simply wrappers around underlying input or output streams that transparently provide some extended level of functionality. These streams are typically accessed by methods that are expecting a generic stream, which is a superclass of the filtered streams. Typical extensions are buffering, character translation, and raw data translation. The filtered byte streams are:

- FilterInputStream
- FilterOutputStream

Their constructors are:

FilterOutputStream (OutputStream os)

FilterInputStream (InputStream is)

15.7.8 Buffered Byte Streams

For the byte-oriented streams, a buffered stream extends a filtered stream class by attaching a memory buffer to the I/O stream. This buffer allows Java to do I/O operations on more than a byte at a time, thereby improving performance. Because the buffer is available, skipping, marking, and resetting of the stream become possible. The buffered byte stream classes are:

- BufferedInputStream
- BufferedOutputStream
- PushbackInputStream

15.7.8.1 BufferedInputStream

Java's BufferedInputStream class allows you to "wrap" any InputStream into a buffered stream to improve performance. BufferedInputStream has two constructors:

```
BufferedInputStream (InputStream inputStream)
BufferedInputStream (InputStream inputStream, int bufSize)
```

The first form creates a buffered stream using a default buffer size. In the second, the size of the buffer is passed in bufSize. Use of sizes that are multiples of a memory page, a disk block, and son, can have a significant positive impact on performance. A good guess for a size is around 8,192 bytes, and attaching even a rather small buffer to an I/O stream is always a good idea. That way, the low-level system can read blocks of data from the disk or network and store the results in your buffer. Thus, even if you are reading the data a byte at a time out of the InputStream, you will be manipulating fast memory most of the time.

Buffering an input stream provides the foundation required to support moving backward in the stream of the available buffer. Beyond the read() and skip() methods implemented in any InputStream, BufferedInputStream also supports the mark() and reset() methods. This support is reflected by the BufferedInputStream.markSupported() returning true.

15.7.8.2 Buffered Input Example

The following example contrives a situation where we can use mark() to remember where we are in an input stream and later use reset() to get back there. This example is parsing a stream for the HTML entity reference for the "copyright" symbol. Such a reference begins with an ampersand (&) and ends with a semicolon (;) without any intervening whitespace. The sample input has two ampersands to show the case where the reset() happens and where it does not.

15.8 The Character Streams

While th byte stream classes provide sufficient functionality to handle any type of I/O operation, they cannot work directly with Unicode characters. Since one of the purposes of Java is to support the "write once, run anywhere" philosophy, it was necessary to include direction I/O support for characters. In this section, several of the character I/O classes are discussed.

At the top of the character stream hierarchies are the

- Reader
- Writer

abstract classes.

15.8.1 Reader

Reader is an abstact class that defines Java's model of streaming character input. It implements the AutoCloseable, Closeable, and Readable interfaces. All of the methods in this class (except markSupported()) will throw an IOException on error conditions.

Reader Methods

abstract void close()

Closes the input source. Further read attempts will general an IOException.

void mark(int numChars)

Places a mark at the current point in the input stream that will remain valid until numChars characters are read.

boolean markSupported()

Returns true if mark()/reset() are supported on this stream.

int read(char buffer[])

Attempts to read up to *buffer.length* characters into *buffer* and returns the actual number of characters that were successfully read. -1 is returned when an attempt is made to read at the end of the stream.

int read(CharBuffer buffer)

Attempts to read characters into *buffer* and returns the actual number of characters that were successfully read. -1 is returned when an attempt is made to read at the end of the stream.

abstract int read(char buffer[], int offset, int numChars)

Attempts to read up to *numChars* characters into *buffer* starting at *buffer[offset]*, returning the number of characters successfully read. -1 is returned whn an attempt is made to read at the end of the stream.

boolean read()

Returns true if the next input request will not wait. Otherwise, it returns false.

void reset()

Resets the input pointer to the previously set mark.

long skip(long numChars)

Skips over *numChars* characters of input, returning the number of characters actually skipped.

Table 15.5: The Methods Defined by Reader

15.8.2 Writer

Writer is an abstract class that defines streaming character output. It implements the AutoCloseable, Closeable, Flushable, and Appendable interfaces. All of the methods in this class throw an IOException in the case of errors.

Writer Methods

Writer append(char ch)

Appends ch tot he end of the invoking output stream. Returns a reference to the invoking stream.

Writer append(CharSequence chars)

Appends *chars* to the end of the invoking output stream. Returns a reference to the invoking stream.

Writer append(CharSequence chars, int begin, int end)

Appends the subrange of *chars* specified by *begin* and *end* - 1 to the end of the invoking output stream. Returns a reference to the invoking stream.

abstract void close()

Closes the output stream. Further write attempts will generate an IOException.

abstract void flush()

Finalizes the output state so that any buffers are cleared (it flushes the output buffers).

void write(int ch)

Writes a single character to the invoking output stream. The parameter is an int, which allows you to call write() with an expression without have to case it back to char. However, only the low-order 16 bits are written.

void write(char buffer//)

Writes a complete array of characters to the invoking output stream.

abstract void(char buffer[], int offset, int numChars)

Writes a subrange of *numChars* characters from the array *buffer*, beginning at *buffer*/offset/ to the invoking output stream.

void write(String str)

Writes str to the invoking output stream.

void write(String str, int offset, int numChars)

Writes a subrange of *numChars* characters from the string *str*, beginning at the specified *offset*

Table 15.6: The Methods Defined by Writer

15.8.3 FileReader

The FileReader class creates a Reader that you can use to read the contents of a file. Two commonly used constructors are:

FileReader (String filePath)

FileReader (File fileObj)

Either can throw a FileNotFoundException.

Example Reading Lines From a File

This example shows how to read lines from a file and display them on the standard output device. It reads its own source file, which must be in the current directory.

The following table lists called chunk definition points.

15.8.3.1 FileReaderDemo TryWtihResources FileReader

```
<FileReaderDemo TryWithResources FileReader> =
   try (FileReader fr = new FileReader("FileReaderDemo.java")) {
    int c;
   while ((c = fr.read()) != -1)
        System.out.print((char) c);
}
```

This chunk is called by {FileReaderDemo.java}; see its first definition at "FileReader", page 110.

15.8.3.2 Catch IOException

```

   catch (IOException e) {
     System.out.println("I/O Error: " + e);

See "Buffered Reader Demo", page 111.
See "FileReader", page 110.
```

15.8.4 FileWriter

FileWriter creates a Writer that you can use to write to a file. Four commonly used constructors are:

```
FileWriter (String filePath)
```

```
FileWriter (String filePath, boolean append)
FileWriter (File fileObj)
FileWriter (File fileObj, boolean append)
```

They can all throw an IOException. If append is true, then output is appended to the end of the file. Creation of a FileWriter is not dependent on the file already existing. FileWriter will create the file before opening it for output when you create the object. In the case where you attept to open a read-only file, an IOException will be thrown.

15.8.5 CharArrayReader

15.8.6 CharArrayWriter

15.8.7 BufferedReader

BufferedReader improves performance by buffering input. It has two constructors:

```
BufferedReader (Reader inputStream)
BufferedReader (Reader inputStream, int bufSize)
```

The first form creates a buffered character stream using a default buffer size. In the second, the size of the buffer is passed in *bufSize*. Closing a BufferedReader also causes the underlying stream specified by *inputStream* to be closed.

Buffering an input character stream provides the foundation required to support moving backward in the stream within the available buffer. To support this, BufferedReader implements the mark() and reset() methods, and BufferedReader.markSupported() returns true.

JDK 8 added a new method to BufferedReader called lines(). It returns a Stream reference to the sequence of lines read by the reader. (Stream is part of the stream API discussed in Chapter 23 "The Stream API", page 122.

15.8.8 Buffered Reader Demo

This example reworks the BufferedInputStream example (see Section 15.7.8.2 "Buffered Input Example", page 103) so that it uses a BufferedReader character stream rather than a buffered byte stream. It uses the mark() and reset() methods to parse a stream for the HTML-entity reference for the copyright symbol. Such a reference begins with an ampersand (&) and ends with a semicolon (;) without any intervening whitespace. The sample has two ampersands to show the case where the reset() happens and where it does not.

```

15.8.8.2 BufferedReaderDemo Buffer

Notice that this implementation uses a char buffer, with a getChars() method to transfer the string characters, while the BufferedInputStream implementation uses a byte buffer, and a getBytes() method to transfer the string bytes. See Section 15.7.8.8 "BufferedInputStreamDemo Buffer", page 106.

```
<BufferedReaderDemo Buffer> =
    char buf[] = new char[s.length()];
    s.getChars(0, s.length(), buf, 0);
```

This chunk is called by *AufferedReaderDemo Instance Variables*; see its first definition at "BufferedReaderDemo Instance Variables", page 112.

15.8.8.3 BufferedReaderDemo TryWithResources BufferedReader

Notice that the Switch code is identical to the byte stream example.

```
<BufferedReaderDemo TryWithResources BufferedReader> ≡

try ( BufferedReader f = new BufferedReader(in) ) {
    while ( (c = f.read()) != -1 ) {
        <BufferedInputStreamDemo Switch on Character>

```

This chunk is called by {BufferedReaderDemo.java}; see its first definition at "Buffered Reader Demo", page 111.

The called chunk < BufferedInputStreamDemo Switch on Character> is first defined at "BufferedInputStreamDemo Switch on Character", page 105.

15.8.9 BufferedWriter

A BufferedWriter is a Writer that buffers output. Using a BufferedWriter can improve performance by reducing the number of times data is actually physically written to the output device. A BufferedWriter has these constructors:

```
BufferedWriter (Writer outputStream)
BufferedWriter (Writer outputStream, int bufSize)
```

15.9 The Console Class

15.10 Serialization

Serialization is the process of writing the state of an object to a byte stream. This is useful when you want to save the state of your program to a persistent storage area, such as a file. At a later time, you may restore these objects by using the process of deserialization.

Assume that an object to be serialized has references to other objects, which, in turn, have references to still more objects. This set of objects and the relationships among them form a directed graph. There may also be circular references within this object graph. Objects may also contain references to themselves. The object serialization and deserialization facilities have been designed to work correctly in these scenarios. If you attempt to serialize an object at the top of an object graph, all of the other referenced objects are recurseively located and serialized. Similarly, during the process of deserialization, all of these objects and their references are correctly restored.

15.10.1 Serializable

Only an object that implements the Serializable interface can be saved and restored by the serialization facilities. The Serializable interface defines no members. It is simply used to indicate that a class may be serialized. If a class is serializable, all of its subclasses are also serializable.

Variables that are declared as transient are not saved by the serialization facilities. Also static variables are not saved.

15.10.2 Externalizable

The Java facilities for serialization and descrialization have been designed so that much of the work to save and restore the state of an object occurs automatically. However, there are cases in which the programmer may need to have control over these processes. The Externalizable interface is designed for these situations.

The Externalizable interface defines these two methods:

void readExternal (ObjectInput inStream) throws IOException, ClassNotFoundException void writeExternal (ObjectOutput outStream throws IOException

25 Reflection

Reflection is the ability of software to analyze or modify itself at runtime rather than at compile time. This is provided by the <code>java.lang.reflect</code> package and elements in <code>Class</code>. Beginning with JDK 9, <code>java.lang.reflect</code> is part of the <code>java.base</code> module. Reflection allows you to analyze a software component and describe its capabilities dynamically at run-time rather than at compile time. For example, by using reflection, you can determine what methods, constructors, and fields a class supports.

Drawbacks of Reflection

Because reflection is dynamic, the java virtual machine is unable to make certain optimizations and could therefor run slower. Also, since reflection allows code to perform operations that would be illegal in non-reflective code, such as accessing private fields and methods, the use of reflection can result in unexpected behavior. Reflection breaks abstractions.

25.1 java.lang.reflect Package

The package java.lang.reflect includes several interfaces. Of special interest is Member, which defines methods that allow you to get information about field, constructor, or method of a class. There are also ten classes in this package.

Classes Defined in java.lang.reflect

AccessibleObject

Allows you to bypass the default access control checks

Array Allows you to dynamically create and manipulate arrays

Constructor

Provides information about a constructor

Executable

An abstract superclass extended by Member and Constructor

Field Provides information about a field

Method Provides information about a method

Modifier Provides information about class and member access modifiers

Parameter

Provides information about parameters

Proxy Supports dynamic proxy classes

ReflectPermission

Allows reflection of private or protected members of a class

Table 25.1: Classes Defined in java.lang.reflect

25.2 Classes and Reflection

For every type of object, the Java virtual machine instantiates an immutable instance of java.lang.Class which provides methods to examine the runtime properties of the object including its members and type information.

Class also provides the ability to create new classes and objects. Most importantly, it is the entry point for all of the Reflective APIs.

25.2.1 Retrieving Class Objects

The entry point for all reflection operations is <code>java.lang.Class</code>. None of the classes in <code>java.lang.reflect</code> have public constructors. To get to these classes, it is necessary to invoke appropriate methods on <code>Class</code>. There are several ways to get a <code>Class</code> depending on whether the code has access to an object, the name of the class, a type, or an existing <code>Class</code>.

25.2.1.1 Object.getClass()

If an instance of an object is available, then the simplest way to get its Class is to invoke Object.getClass().

String.getClass()

```
Class c = "foo".getClass();
returns the Class for String;
```

System.console.getClass()

```
Class c = System.console().getClass();
returns the Class corresponding to java.io.Console.2
```

Enum.getClass()

```
enum E { A, B }
Class c = A.getClass();
```

A is an instance of the enum E; thus, getClass() returns the Class corresponding to the enumeration type E.

Array.getClass()

Since arrays are Objects, it is possible to invoke getClass() on an instance of an array. The returned Class corresponds to an array with component type byte.

```
import java.util.HashSet;
import java.util.Set;

Set<String> s = new HashSet<String>();
Class c = s.getClass();
```

java.util.Set is an interface to an object of type java.util.HashSet. The value returned by getClass() is the class corresponding to java.util.HashSet.

¹ with the exception of java.lang.reflect.ReflectPermission.

² There is a unique console associated with the virtual machine which is returned by the static method System.console().

25.2.1.2 The .class Syntax

If the type is available, but there is no instance, then it is possible to obtain a Class by appending .class to the name of the type. This is also the easiest way to obtain the Class for a primitive type.

Primitive.class

```
boolean b;
Class c = b.getClass(); // compile-time error
Class c = boolean.class: // correct
```

The statement 'boolean.getClass()' would produce a compile-time error because a boolean is a primitive type and cannot be dereferenced. The .class syntax returns the Class corresponding to the type boolean.

Type.class

```
Class c = java.io.PrintStream.class;
```

The variable c will be the Class corresponding to the type java.io.PrintStream.

Multi-dimensional Array

```
Class c = int[][].class;
```

The .class syntax may be used to retrieve a Class corresonding to a multi-dimensional array of a given type.

25.2.1.3 Class.forName() and Class.getName() Methods

If the fully-qualified name of a class is available, it is possible to get the corresponding Class using the static method Class.forName(). This cannot be used for primitive types.

The syntax for names of array classes is described by Class.getName(). This syntax is applicable to references and primitive types.

forName()

```
Class c = Class.forName("com.duke.MyLocalServiceProvider");
```

This statement will create a class from the given fully-qualified name.

getName()

```
FIXME: should these be getName() instead of forName()?
    Class cDoubleArray = Class.forName("[D");
    Class cStringArray = Class.forName("[[Ljava.lang.String;");
```

The variable cDoubleArray will contain the Class corresponding to an array of primitive type double (i.e., the same as double[].class. The cStringArray variable will contain the Class corresponding to a two-dimensional array of String (i.e., identical to String[]].class).

25.2.1.4 TYPE Field for Primitive Type Wrappers

The .class syntax is a more convenient and the preferred way to obtain the Class for a primitive type; however, there is another way to acquire the Class. Each of the primitive types and void has a wrapper class in java.lang that is used for boxing of primitive types

to reference types. Each wrapper class contains a field name TYPE which is equal to the Class for the primitive type being wrapped.

Wrapper TYPE for Primitive

```
Class c = Double.TYPE;
```

There is a class java.lang.Double which is used to wrap the primitive type double whenever an Object is required. The value of Double.TYPE is identical to that of double.class.

Wrapper TYPE for void

```
Class c = Void.TYPE;
```

Void. TYPE is identical to void. class.

25.2.1.5 Methods that Return Classes

There are several Reflection APIs which return classes, but these may only be accessed if a Class has already been obtained, either directly or indirectly.

Class.getSuperClass()

Returns the super class for the given class.

```
Class c = javax.swing.JButton.class.getSuperclass();
```

Class.getClasses()

Returns all the public classes, interfaces, and enums that are members of the class including inherited members.

```
Class<?>[] c = Character.class.getClasses();
```

Class.getDeclaredClasses()

Returns all of the classes interfaces, and enums that are explicitly declared in this class.

```
Class<?>[] c = Character.class.getDeclaredClasses();
```

Class.getDeclaringClass()

```
java.lang.reflect.Field.getDeclaringClass()
java.lang.reflect.Method.getDeclaringClass()
java.lang.reflect.Constructor.getDeclaringClass()
```

Returns the Class in which these members were declared. Anonymous Class Declarations will not have a declaring class but will have an enclosing class.

```
import java.lang.reflect.Field;

Field f = System.class.getField("out");
   Class c = f.getDeclaringClass();

The field out is declared in System.
   public class MyClass {
      static Object o = new Object() {
         public void m() {}
      };
```

```
static Class<c> = o.getClass().getEnclosingClass();
}
The declaring class of the anonymous class defined by o is null
Class.getEnclosingClass()
Returns the immediately enclosing class of the class.
    Class c = Thread.State.class().getEnclosingClass();
The enclosing class of the enum Thread.State is Thread.
    public class MyClass {
        static Object o = new Object() {
            public void m() {}
            };
        static Class<c> = o.getClass().getEnclosingClass();
}
The anonymous class defined by o is enclosed by MyClass.
